# Contributors to Volume 3

## MARIANO M. ALIMURUNG

Professor of Medicine, Chief of Cardiovascular Section in the Faculty of Medicine, University of Santo Tomás, Manila, Philippine Islands. Founder and first President of the Philippine Heart Association; founder of the *Philippine Heart Journal*. Author of numerous articles in the field of cardiology, an Editor of *Cardiology*

## THOMAS G. BAFFES

Associate in Department of Surgery, Northwestern University, Medical School; affiliated with Children's Memorial Hospital, Chicago. Author of several papers on the surgery of congenital heart disease.

## CHARLES P. BAILEY

Professor and Head of Department of Thoracic Surgery, Northwestern University, Medical School, Chicago.

Author of numerous publications on the surgery of acquired valvular defects; Editor of a book on cardiac surgery.

## PAUL S. BARKER

Professor of Internal Medicine, University of Michigan, Medical School, and Attending Physician, University of Michigan Hospital, Ann Arbor.

## SAMUEL BELLET

Professor of Clinical Cardiology, University of Pennsylvania, Philadelphia.

Director  
General  
Univ.

electrocardiography and Clinical Disorders of the Heart Beat, and of numerous articles on cardiology. Member of Editorial Board, formerly Associate Editor of *Circulation*

## AARON B. BENCHIMOL

Associate Professor of Cardiology, University of Rio de Janeiro, and Chief of Service of Cardiology, Hospital dos Servidores do Estado, Rio de Janeiro. Past President of American College of

cardiology, American Heart Association, and the Society of Cardiology

## HERMAN T. BLUMENTHAL

Associate Professor of Pathology, St. Louis University, School of Medicine, and Director of Laboratories, Jewish Hospital of St. Louis; formerly held several positions in the U.S. Army

and several articles on arteriosclerosis. Recipient of the A. Berg Prize in Bacteriology and Immunology (1941).

## HOUCK E. BOLTON

Instructor in Department of Thoracic Surgery, Hahnemann Medical College and Hospital of Philadelphia. Author of several articles and of textbook chapters on cardiac surgery.

## LINN J. BOYD

Professor of Medicine, New York University, Post-Graduate Medical School, formerly Chairman of Department of Medicine and Professor of Pharmacology, New York Medical College, Flower and Fifth Avenue Hospitals, New York. Coauthor of three books of cardiology. Editor in Chief of the *Bulletin of the New York Medical College*.

## EUGENE BRAUNWALD

Clinical Associate in Laboratory of Cardiovascular Physiology, National Heart Institute, Bethesda, member of Department of Medicine, Johns Hopkins Hospital, Baltimore.

## ALDO CALO

Formerly Assistant Professor of Medicine, University of Rome, Italy. Author of two books, dealing with phonocardiography, and of many articles on cardiovascular subjects.

## EDUARDO J. CANABAL

Docente de Fisiologia

videt

Clínica

society

and the Society of Cardiology

of Uruguay. Author of several papers dealing particularly with *Echinococcus* heart disease

**PHILIPPE V. CARDON, Jr.**

Surgeon of U.S. Public Health Service, National Institute of Mental Health, Bethesda; Instructor in Medicine, Georgetown University, School of Medicine, Washington, D.C.; formerly Instructor in Medicine, New York University, College of Medicine, and Cornell University, Medical College, New York. Coauthor of *Life Stress and Essential Hypertension*.

**PETER W. CONRAD**

Instructor in Surgery, Georgetown University, School of Medicine, Washington, D.C.

**ANTONIO COSTA**

Professor of Pathological Anatomy, University of Florence, and Pathologist of the City Hospital, Florence, Italy; formerly Professor of Pathology, Universities of Sassari, Perugia, and Pisa. Author of several studies on congenital heart disease and atherosclerosis. Founder and Editor of *Archivio de Vecchi* for pathology.

**CHARLES W. CRUMPTON**

Associate Professor of Medicine, Director of the Cardiovascular Research Laboratory, and Program Director for the National Heart Institute, University of Wisconsin, Medical School, Madison, formerly Fellow in Pharmacology and Instructor of Medicine, University of Pennsylvania, School of Medicine, Philadelphia.

**J. FRANCIS DAMMANN, Jr.**

Associate Professor of Surgical Cardiology, University of Virginia, School of Medicine, Charlottesville; formerly Assistant Professor of Pediatrics, University of Southern California, School of Medicine, Los Angeles. Author of many articles dealing especially with congenital heart disease.

**RALPH A. DETERLING, Jr.**

Professor and Chairman of Department of Surgery, Tufts University, School of Medicine and Surgeon in Chief at New England Center Hospital, Boston, formerly Associate Clinical Professor of Surgery, Columbia University, College of Physicians and Surgeons and Associate Attending Surgeon at Presbyterian Hospital, New York. Author of many papers in the fields of vascular surgery, renal hypertension, aortography, vascular grafts, and hypothermia. Associate Editor of *Journal of Cardiovascular Surgery*.

**ANTONI M. DIEHL**

Assistant Professor of Pediatrics and Pediatric Cardiologist, University of Kansas, School of Medicine, Medical Director of Children's Convalescent Center, Kansas City. Author of several articles in the fields of congenital heart disease and rheumatic fever.

**JORGE DIGHERO**

Assistant Professor of Medicine, Faculty of Medicine and Chief of Cardiology Laboratory, How-

pital dos Clinicas, Montevideo. Past President of Cardiological Society of Uruguay. Author of numerous articles, dealing particularly with *Echinococcus* heart disease.

**WILLIAM S. DYE**

Clinical Assistant Professor of Surgery, University of Illinois, College of Medicine, Chicago, Attending Surgeon, Veterans Administration Hospital, Hines. Author of articles in the field of cardiovascular surgery.

**HERBERT ELIAS**

Clinical Professor of Medicine, New York Medical College, Flower and Fifth Avenue Hospitals, New York, formerly Professor of Internal Medicine, University of Vienna, and Attending Physician in various hospitals in Vienna. Past President of the Virchow Society of New York. Author of numerous articles on congestive heart failure and constrictive pericarditis.

**MARY ALLEN ENGLE**

Assistant Professor of Pediatrics, Cornell University, Medical College and Assistant Attending Pediatrician, New York Hospital, New York, formerly Instructor of Pediatrics at Johns Hopkins University, School of Medicine, Baltimore, and at Cornell University, Medical College. Author of numerous publications in the field of pediatrics.

**BERNARD F. FETTER**

Assistant Professor of Medicine, Duke University, School of Medicine, and Associate Pathologist, Duke Hospital, Durham.

**ALFRED P. FISHMAN**

Assistant Professor of Medicine, Columbia University, College of Physicians and Surgeons, affiliated with Presbyterian and Bellevue Hospitals, New York. An Established Investigator of the American Heart Association. Author of *Cardiology Notebook* and of many scientific papers.

**FREDERICK G. GILLICK**

Dean of Creighton University, School of Medicine, Omaha, he has held numerous cardiology positions in the U.S. Public Health Service. Author of several articles on cardiology including electrokymography.

**ROBERT P. GLOVER**

Assistant Professor of Clinical Surgery, University of Pennsylvania, School of Medicine, and Director of Thoracic and Cardiovascular Research Laboratory, Presbyterian Hospital, Philadelphia. Author of numerous articles and of chapters in textbooks on cardiovascular surgery. Member of the Editorial Board of *American Journal of Cardiology* and of *Circulation*.

**FRANCO GOBBI**

Research Fellow in Medicine, Tufts University, School of Medicine, Boston, and Attending Physician, St. Elizabeth Hospital, Boston. Recipient of a Fulbright Scholarship. Presently on Department of

of Medical Pathology, University of Modena, Italy.

#### JACOB S. GOLDEN

Associate Professor of Medicine, Northwestern University, Medical School, Attending Physician, Michael Reese and Veterans Administration Hospitals, Chicago; Consultant in Internal Medicine, US Public Health Service Hospital, formerly Attending Physician, Cook County Hospital, and Professor, Cook County Graduate School of Medicine, Chicago. Author of numerous studies in cardiovascular research.

#### IRA GORE

Clinical Associate in Pathology, Harvard University, Medical School, Chief of Laboratory Service, Veterans Administration Hospital; and Senior Associate in Pathology, Peter Bent Brigham Hospital, Boston, formerly at Michael Reese Hospital, Chicago. Author of articles dealing with pathologic processes in cardiovascular diseases.

#### RICHARD GORLIN

Instructor in Medicine, Howard University, Medical School, and Junior Associate in Medicine, Peter Bent Brigham Hospital, Boston, Honorary Associate in Medicine, St. Thomas Hospital, London, formerly in charge of Cardiopulmonary Laboratory, US Naval Hospital, Portsmouth, Virginia. Author of articles on cardiac catheterization and mitral valve disease, Associate Editor of the cardiovascular volume, *Methods in Medical Research*.

#### TOM R. HAMILTON

in conjunction with streptococcal infections and rheumatic fever. Editor of book, *Medical Microbiology*.

#### J. HANSON

#### OLGA HARING

Research Associate in Surgery, Northwestern University, Medical School, Chicago; formerly Director of Health Center and Chief of Ward of Cardiology, General Hospital, Managua, Nicaragua; Assistant in Medicine and Cardiology, Chicago Medical School, and Associate Attending Cardiologist, La Rabida Sanitarium, Chicago.

#### DWIGHT E. HARKEN

Associate Clinical Professor of Surgery, Harvard University, Medical School, and Surgeon, Peter

Bent Brigham Hospital, Boston; formerly Howe Surgeon, Bellevue Hospital, New York, and Lieutenant Colonel, Director of Thoracic Surgery Course for Medical Officers. Author of numerous articles on surgery of the mitral valve and on treatment of rheumatic conditions.

#### ROBERT HEIM DE BALSAC

Formerly Chief of Laboratory, Cardiology Clinic, Broussais Hospital, Paris, and Cardiologist, Lannelongue Surgical Center. Author of chapters in *Roenngenology of the Heart and Vessels* and in *Congenital Heart Diseases*; he has published articles on roentgen kymography. An Editor of *Cardiology*.

#### EUGENE HILDEBRAND

Instructor in Pathology, University of Colorado, School of Medicine, Pathologist, Mercy Hospital, and Consultant in Pathology, Denver General Hospital, Denver; formerly at Northwestern University, Medical School, Chicago.

#### WILLIAM M. HITZIG

Assistant Professor of Clinical Medicine, Columbia University, College of Physicians and Surgeons, and Associate Physician, Mount Sinai Hospital, New York. Known for studies on respiration time, venous pressure, and cardiac handles.

#### MAY HOLZMANN

Associate Assistant in Cardiology in Department of Medicine, University of Zurich. Author of a *Textbook of Electrocardiography* and of several chapters dealing with arrhythmias in German textbooks.

#### CHARLES A. HUFNAGEL

Professor of Surgical Research, and Professor of Surgery, and Director of Experimental Laboratory, Georgetown University Medical Center, Consultant in several hospitals in Bethesda and Washington, D.C. He has done pioneering work

for aortic insufficiency.

#### ALDO JACONO

Research Assistant in Division of Cardiology, Chicago Medical School, Chicago; formerly Assistant in Department of Medicine, Medical School of Naples, Italy.

#### A. GREGORY JAMESON

Assistant Professor of Pediatrics, Columbia University, College of Physicians and Surgeons and Director of the Cardiovascular Laboratory at Presbyterian Hospital, New York. He is also associated as Attending or Consultant of the First Medical Division at Bellevue Hospital, at Brooklyn Hospital, and at the Veterans Administration Hospital, Castle Point, New York.

#### EUGENIO JONA

Assistant in Institute of Medical Pathology, University of Torino, Italy, formerly Research Assistant, Division of Cardiology, Chicago Medical School. A Fulbright Scholar.

of Uruguay. Author of several papers dealing particularly with *Echinococcus* heart disease.

**PHILIPPE V. CARDON, Jr.**

Surgeon of U.S. Public Health Service, National Institute of Mental Health, Bethesda. Instructor in Medicine, Georgetown University, School of Medicine, Washington, D.C.; formerly Instructor in Medicine, New York University, College of Medicine, and Cornell University, Medical College, New York. Coauthor of *Life Stress and Essential Hypertension*.

**PETER W. CONRAD**

Instructor in Surgery, Georgetown University, School of Medicine, Washington, D.C.

**ANTONIO COSTA**

Professor of Pathological Anatomy, University of Florence, and Pathologist of the City Hospital Florence, Italy; formerly Professor of Pathology, Universities of Sassari, Perugia, and Pisa. Author of several studies on congenital heart disease and atherosclerosis. Founder and Editor of *Archivio de Vecchi* for pathology.

**CHARLES W. CRUMPTON**

Associate Professor of Medicine, Director of the Cardiovascular Research Laboratory, and Program Director for the National Heart Institute, University of Wisconsin, Medical School, Madison; formerly Fellow in Pharmacology and Instructor of Medicine, University of Pennsylvania, School of Medicine, Philadelphia.

**J. FRANCIS DAMMANN, Jr.**

Associate Professor of Surgical Cardiology, University of Virginia, School of Medicine, Charlottesville; formerly Assistant Professor of Pediatrics, University of Southern California, School of Medicine, Los Angeles. Author of many articles dealing especially with congenital heart disease.

**RALPH A. DETERLING, Jr.**

Professor and Chairman of Department of Surgery, Tufts University, School of Medicine and Surgeon in Chief at New England Center Hospital, Boston, formerly Associate Clinical Professor of Surgery, Columbia University, College of Physicians and Surgeons and Associate Attending Surgeon at Presbyterian Hospital, New York. Author of many papers in the fields of

pital dos Clinicas, Montevideo. Past President of Cardiological Society of Uruguay. Author of numerous articles, dealing particularly with *Echinococcus* heart disease.

**WILLIAM S. DYE**

Clinical Assistant Professor of Surgery, University of Illinois, College of Medicine, Chicago. Attending Surgeon, Veterans Administration Hospital, Hines. Author of articles in the field of cardiovascular surgery.

**HERBERT ELIAS**

Clinical Professor of Medicine, New York Medical College, Flower and Fifth Avenue Hospitals, New York, formerly Professor of Internal Medicine, University of Vienna, and Attending Physician in various hospitals in Vienna. Past President of the Virchow Society of New York. Author of numerous articles on congestive heart failure and constrictive pericarditis.

**MARY ALLEN ENGLE**

Assistant Professor of Pediatrics, Cornell University, Medical College and Assistant Attending Pediatrician, New York Hospital, New York, formerly Instructor of Pediatrics at Johns Hopkins University, School of Medicine, Baltimore, and at Cornell University, Medical College. Author of numerous publications in the field of pediatrics.

**BERNARD F. FETTER**

Assistant Professor of Medicine, Duke University, School of Medicine, and Associate Pathologist, Duke Hospital, Durham.

**ALFRED P. FISHMAN**

Assistant Professor of Medicine, Columbia University, College of Physicians and Surgeons, affiliated with Presbyterian and Bellevue Hospitals, New York. An Established Investigator of the American Heart Association. Author of *Cardiology Notebook* and of many scientific papers.

**FREDERICK C. GILLOCK**

Dean of Creighton University, School of Medicine, Omaha. He has held numerous cardiology positions in the U.S. Public Health Service. Author of several articles on cardiology including electrocardiography.

**ROBERT P. GLOVER**

Assistant Professor of Clinical Surgery, University of Pennsylvania, School of Medicine, and Director of Thoracic and Cardiovascular Research Laboratory, Presbyterian Hospital, Philadelphia. Author of numerous articles and of chapters in textbooks on cardiovascular surgery. Member of the Editorial Board of *American Journal of Cardiology* and of *Cardiology*.

**FRANCO GOBBI**

Research Fellow in Medicine, Tufts University, School of Medicine, Boston, and Research Associate, St. Elizabeth Hospital, on leave of absence under a Fulbright Scholarship, from Department

**ANTONI M. DIEHL**

Assistant Professor of Pediatrics and Pediatric Cardiologist, University of Kansas, School of Medicine, Medical Director of Children's Convalescent Center, Kansas City. Author of several articles in the fields of congenital heart disease and rheumatic fever.

**JORGE DIGHIERO**

Assistant Professor of Medicine, Faculty of Medicine and Chief of Cardiology Laboratory, How-

Author of several papers on rheumatic valvular disease.

#### THOMAS J. O'NEILL

Associate Professor of Thoracic Surgery, Women's Medical College of Pennsylvania, and affiliated with Episcopal and Graduate Hospitals of the University of Pennsylvania, Philadelphia. Author of articles on surgery of rheumatic valvular disease, Contributing Editor to *Cyclopedia of Medicine* and Associate Editor of *Clinical Cardiology*.

#### CORNELIO PAPP

Clinical Assistant, Cardiac Department of London Chest Hospital. Author of several articles dealing especially with arrhythmias.

#### WALTER PRIEST

Associate Professor of Medicine, Northwestern University, Medical School, and Senior Attending Physician, Wesley Memorial Hospital, Chicago. Past President, American College of Cardiology. Author of several articles on bacterial endocarditis and myocardial infarction. Member of Advisory Board and an Editor of *Cardiology*.

#### ANIS RASSI

Cardiologist in Chief at the Hospital Rassi, Goiania, Brazil.

#### DANIEL ROUTIER

Attending Physician, Paris Hospital. Honorary President, French Association of Cardiology of the Arc.

#### ALBERT I. RUBENSTONE

Assistant Clinical Professor of Pathology, University of Illinois, College of Medicine, and Associate Pathologist and Assistant Director of Department of Pathology.

#### OTTO SAPHIR

Clinical Professor of Pathology, University of Illinois, College of Medicine, and Director of Department of Pathology.

#### STANLEY I. SARNETZ

Professor of Medicine, Johns Hopkins University, School of Medicine, Baltimore, Associate Professor of Physiology, Harvard School of Public Health, Boston. Author of over 100 publications in the fields of acute pulmonary edema, shock, cardiac physiology, and valvular diseases, an Editor of *Cardiology*.

#### J. GORDON SCANNELL

Assistant Clinical Professor of Surgery, Harvard University, Medical School, and Associate Visiting Surgeon, Massachusetts General Hospital, Boston. Author of numerous publications in cardiology.

#### DAVID SCHIERF

Professor of Clinical Medicine and Attending Physician, New York Medical College, Flower and Fifth Avenue Hospitals, New York, formerly Privat Dozent in Department of Medicine, University of Vienna. Coauthor of three books, *Extrasystoles and Allied Arrhythmias*, *Cardiovascular Diseases*, and *Clinical Electrocardiography*.

#### PAUL SCHLESINGER

Assistant in Cardiology, Fifth Medical Clinic, University of Brazil, Rio de Janeiro. Author of publications on beriberi and nutritional heart disease.

#### JOHN SCHWEDEL

Assistant Clinical Professor of Medicine, University of Illinois, College of Medicine, and Associate Pathologist and Assistant Director of Department of Pathology.

#### H. WILLIAM SCOTT, Jr.

Head of Department of Surgery, Vanderbilt University, School of Medicine, Nashville, formerly Associate Professor of Surgery, Johns Hopkins University, School of Medicine, Baltimore.

#### C. GORDON SELL

Assistant Clinical Professor of Medicine, University of Illinois, College of Medicine, and Associate Pathologist and Assistant Director of Department of Pathology.

#### LOUIS H. SIGLER

Consulting Cardiologist at Coney Island and Rockaway Beach Hospitals, Consulting Cardiologist at Adelphi Hospital, Brooklyn, formerly Instructor of Medicine, New York Post-Graduate Medical School of Columbia University. Author of books, *Cardiovascular Disease* and *The Electrocardiogram*.

#### EARL N. SILBER

Assistant Clinical Professor of Medicine, Chicago Medical School, and Adjunct Attending Physician, Michael Reese Hospital, Chicago. Author of several papers in various fields of cardiology, particularly myocarditis.

#### HUTTON D. SLADE

Director of Laboratories and Chief of Microbiology, Rheumatic Fever Research Institute, an Established Investigator of the American Heart Association. Author of publications on hemolytic streptococcus.

#### DEMETRIO SODI PALLARES

Professor of Cardiovascular Clinic, University of Brazil, Rio de Janeiro.

## ORMAND C. JULIAN

Associate Professor of Surgery, University of Illinois, College of Medicine, Attending Surgeon, Presbyterian and St. Luke's Hospitals, Chicago. Known for his work in cardiac surgery with hypothermia and cardiac bypass.

## KARL EUGENE KARLSON

Professor of Surgery, State University of New York, Downstate Medical Center and Attending Surgeon at Kings County Hospital, Brooklyn.

## ELISABETH KAVEGGIA

Fellow at Congenital Heart Research Center, Hektoen Institute for Medical Research, Chicago, formerly Assistant Professor of Pediatrics, University of Budapest, Hungary.

## JOHN S. LA DUE

Associate Professor of Clinical Medicine, Cornell University, Medical College; Director of Cardiology, Memorial Center, and Assistant Attending Physician, New York Hospital, New York, formerly Assistant Professor of Medicine, Louisiana State University, Medical School, New Orleans. Author of articles on myocardial infarction and the treatment of thromboembolism.

## CONRAD R. LAM

Surgeon in Charge of Division of Thoracic Surgery, Henry Ford Hospital, Detroit, Doctor Honoris Causa, University of Puebla, Mexico. Editor of *International Symposium on Cardiovascular Surgery*.

## EUGENE LEPESCHKIN

Associate Professor of Experimental Medicine, University of Vermont, College of Medicine, Burlington, an Established Investigator of the American Heart Association, formerly Cardiologist, Bad Nauheim, and Medical Officer, UNRRA, Munich. Author of two books on electrocardiography and of several articles dealing with electrocardiography.

## JEAN LEQUIME

Professor of Cardiology, University of Brussels, Belgium, Chief of Department of Cardiology, St. Peter's Hospital. Author of *Cardiac Output*, coauthor of *Congenital Heart Disease and Heart Failure*. He has published several articles on hemodynamics. Editor in Chief of *Acta Cardiologia*.

## MAURICE LEV

Director of Congenital Heart Disease Research and Training Center of Chicago Heart Association, Hektoen Institute, and Professor of Pathology, Northwestern University, Medical School, Chicago, formerly Pathologist, Mount Sinai Hospital, Miami. He has done outstanding work on congenital heart disease and on the conducting tissues of the heart.

## F. JOHN LEWIS

Professor of Surgery, Northwestern University, Medical School and affiliated with Passavant and Veterans Research Hospital, Chicago, formerly Chief of Thoracic Surgery at Anolia State Hos-

pital, Anolia, Minnesota. Author of articles on surgery, several in the field of hypothermia. Associate Editor of *Surgery, Gynecology, and Obstetrics*.

## A. BARBOSA LIMA

Assistant Professor of Medicine and Chief of the Department of Congenital Heart Diseases, University of São Paulo; Head of the Cardiovascular Service at Hospital Sabbado D'Angelo, São Paulo, Brazil. Formerly Research Associate and Instructor in the Division of Cardiology, Chicago Medical School, and Fellow of the Surgical Physiological Laboratory at Johns Hopkins Hospital, Baltimore.

## CHI KONG LIU

Associate of Clinical Medicine and Research Associate of Division of Cardiology, Chicago Medical School, Head of Cardiac Catheterization Laboratory, Mount Sinai Hospital, Chicago. Co-author of monograph, *Cardiac Pressures and Pulses*, author of chapter, *Emphysema*, in *Clinical Cardiopulmonary Physiology*.

## ALDO A. LUISADA

Professor of Medicine and Director of Division of Cardiovascular Research, Chicago Medical School, Attending Cardiologist, Mount Sinai Hospital, Chicago. Formerly Professor of Medicine, University of Ferrara, Italy, and Instructor of Physiology and Pharmacology and Lecturer in Medicine, Tufts University, School of Medicine, Boston. Author of *Cardiologia*, *Heart*, *Heart Beat*, coauthor of *Intracardiac Phenomena*, and *Treatment of Cardiovascular Emergencies*, author of important contributions in the fields of electrobronchography, phonocardiography, electrokymography, pulse tracings, and acute pulmonary edema. Editor in Chief of *Cardiology*.

## GIANO MAGRI

Associate Professor of Medicine, University of Torino, Italy, formerly Assistant in Department of Medicine, University of Ferrara, Italy, and Research Associate in Division of Cardiology, Chicago Medical School. An Editor of *Cardiology*.

## BLAS MOIA

Extraordinary Professor of Medicine, University of Buenos Aires, Chief of Department of Cardiology, Mejia Hospital, Buenos Aires. Author of three books and over 150 publications in various fields of cardiology. Director of *Revista Argentina de Cardiologia*. An Editor of *Cardiology*.

## ALEXANDER S. NADAS

Assistant Clinical Director of Pediatrics, Harvard University, Medical School, and Cardiologist, Children's Medical Center, Boston. Author of the book, *Pediatric Cardiology*.

## HENRY THOMAS NICHOLS

Instructor and Surgeon in Department of Thoracic Surgery, Hahnemann Medical College and Hospital of Philadelphia, and Adjunct at the Albert Einstein Medical Center, Philadelphia.

# Foreword

This work is at once a landmark in clinical cardiology and an indication of the Golden Age of Medicine in which we now live. Because wondrous things have become commonplace, we can appreciate this age only in retrospect. From rude beginnings it is possible to trace, over the centuries of recorded history, the gradual refinement in skills, the slow accumulation of factual knowledge, and the emergence of a scientific discipline so essential to success in the walks of science. Progress, painfully slow and often faltering till late in the nineteenth century, then began to accelerate at an ever-increasing rate. Within the memory of some now living, individual triumphs in scattered departments of science combined in one mighty triumphant flourish to usher in the modern era. Epidemics, once the scourge of man, were abolished, certain diseases, once relentless in their course, were controlled, old age, once a rarity, became the rule. It is unlikely that within a comparable period of time man will ever again repeat the stupendous feat of doubling his span of life.

Cardiologists, while sharing in these triumphs, saw heart disease assume the lead as a cause of death in many countries. Thus, although gratified by the increased longevity of man, we are nevertheless challenged by the disclosure that the cardiovascular system is now the weakest strand in the thread of life. Indeed, its relative importance in the lives of men appears destined to increase, for there is nothing in sight pointing to a major break-through in the prevention of heart disease in old age.

In sponsoring this encyclopedia, the American College of Cardiology, dedicated to the continuing education of its membership, is simply fulfilling one of its obligations. That this particular obligation weighed more heavily on the minds of some of its officers than on others raised the question of the relative merits of different methods of postgraduate education. We cannot here record the deliberations which finally led to approval of this undertaking, but they reflected the need for putting on record the widening horizons of our knowledge of cardiovascular disease.

That the presentation of information concerning the heart and circulation requires four volumes involving upwards of 250 authors has important implications. It is evidence that narrowing of interest and progress go hand in hand, and that subdivision within the field of cardiology is well established. But this subdivision, so essential for progress, must be reconstituted for those whose clinical responsibilities cover a broad area. In effect this encyclopedia represents such a reconstitution. It contains authoritative information abstracted from an immense mass of medical literature which could not be reviewed effectively by an individual. The organization of this material is based on a logical framework

of Mexico and Chief of Department of Electrocardiography, National Institute of Cardiology, Mexico City. Secretary-Treasurer of Interamerican Society of Cardiology. Author of *New Bases of Electrocardiography*.

#### MARIO STEFANINI

Associate Professor of Medicine and Lecturer in Pharmacology, Tufts University, School of Medicine, and Director of J. Stanton Memorial Laboratories and Hematologist, St. Elizabeth Hospital, Boston; an Established Investigator of American Heart Association.

#### ISRAEL STEINBERG

Associate Clinical Professor of Radiology, and Assistant Clinical Professor of Medicine, Cornell University, Medical College, Assistant Physician and Radiologist, New York Hospital, New York. Coauthor of a text on angiocardiology, author of articles on congenital heart disease

#### JACKSON H. STUCKEY

Assistant Professor of Surgery and Associate Attending Physician at Kings County Hospital and at St. Johns Episcopal Hospital, Brooklyn

#### WARREN J. TAYLOR

Assistant in Surgery, Harvard University, Medical School, and Peter Bent Brigham Hospital, Boston. He has done work on cardiac injuries and on surgery of valvular diseases

#### GEORGE C. TEDESCHI

Associate Professor of Pathology, Boston University, School of Medicine, and Pathologist, Framingham Union Hospital, formerly Head of Department of Pathology, Hahnemann Medical College and Hospital of Philadelphia, and Professor of Pathology, University of Ferrara, Italy. He has published 150 articles including outstanding work on rheumatic carditis.

#### MARIO R. TESTELLI

Research Assistant, National Institute of Cardiology, Mexico City, formerly Resident in Cardiology at Mount Sinai Hospital, Chicago, and Fellow of the Department of Cardiology, Chi-

cago Medical School. Author of several articles on phonocardiography, cardiodynamics, and electrocardiography.

#### SAMUEL A. THOMPSON

Associate Professor of Surgery, New York Medical College, Flower and Fifth Avenue Hospitals, Director of Thoracic Surgery, Metropolitan Hospital, New York. Author of several articles on thoracic surgery, and pericardial poultice

#### RUSTOM JAL VAKIL

Consulting Physician and Cardiologist, at the Medical College and the Grant Medical College, Bombay; formerly Lecturer in Medicine at these colleges. President of the Cardiological Society of India. Author of over 200 papers and especially known for his studies on *Rauwolfia*. An Editor of *Cardiology*. Recipient of the Albert Lasker Award.

#### ARTHUR M. VINEBERG

Lecturer in Surgery, McGill University, and Chief of Sub-Department of Cardiac Surgery, Royal Victoria Hospital, Montreal. Author of numerous articles on surgical intervention in coronary heart disease

#### MISHA S. ZAKS

Clinical Assistant in Department of Neurology and Psychiatry, Northwestern University, Medical School, Chicago, and Instructor, Illinois State Psychopathic Institute. Author of several articles on psychologic studies in rheumatic heart patients

#### ARIO B. ZILLI

Assistant in Department of Medicine, University of Florence, Medical School, Florence, Italy, formerly, Research Assistant in Division of Cardiology, Chicago Medical School

#### PAUL M. ZOLL

Assistant Professor of Medicine, Harvard University, Medical School, and Associate in Medical Research, Beth Israel Hospital, Boston. Author of articles on coronary heart disease and known for his work on the electric pacemaker, an Associate Editor of *Circulation*

# Preface

This work was started as a result of a bold and far-sighted initiative of Dr. Ashton Graybiel, then president of the American College of Cardiology.

The task of editing an encyclopedia of cardiology represents a challenge which is both appealing and frightening.

Among the multitude of books of cardiology which have been published in the last 20 years, the majority belongs to the type of the medium-sized, monographic textbook written by a single author. A few have been written in collaboration by several authors. These, however, do not attempt to be complete and are, moreover, too unsystematic to be helpful. Being of the "fixed-volume" type, they are soon outdated and, therefore, forgotten.

In ancient Greece, *encyclopaedia* meant "instruction in the whole circle, or complete system of learning." In a more restricted sense, encyclopedia means "a system or classification of various branches of knowledge, a subject on which many books have been published." While many encyclopedias of the past have been of the "alphabetical type" (each word to be explained is listed in alphabetical order), others have tried to reconcile system with completeness. Thus, even in the early editions of the *Encyclopaedia Britannica*, the various sciences and arts (such as anatomy or surgery) were "digested into distinct treatises or systems." On the other hand, technical terms were explained in alphabetical order. Older encyclopedias, like Plinius's *Natural History* of the year 77 A.D. (37 books with 2,493 chapters) or *Yung-Lo Ta Tien*, the Chinese encyclopedia of 1403 A.D. (11,095 volumes prepared in four years by over 2,000 scholars), were developed according to system. The latter even included well-known books reproduced without change.

In the opinion of the editor, a modern encyclopedia of cardiology ought to have the following characteristics: (1) It should encompass all available knowledge on the heart and vessels, including history, embryology, anatomy, physiology, physical and technical methods of examination, bacteriology and pathology. (2) It should be of the loose-leaf type, in order to keep abreast of medical progress. It is then possible that some of the readers may prefer to call this a *treatise*.

The principle of extending the work to all kinds of knowledge in the cardiovascular field should not be carried too far in the marginal fringes of medical or technical sciences. This process would divert and distract the attention of the reader and would render consultation too difficult.

which constitutes a resynthesis of the important elements in the field of cardiology.

In using this encyclopedia, the physician must let go of his inclination to be taught, and cultivate the art of selecting new items of information and fitting them into a frame of reference dictated by his needs. This method does require a capacity for mental independence and is effective only in so far as this is exhibited by those for whom the encyclopedia is intended. Admittedly a work of this sort represents a form of communication in which there is much redundancy. At what point will the evil of redundancy equal or exceed the good contained in the message? Herein lies a very real problem with which we should be concerned in the future.

It is noteworthy that in the compilation of this work we are more dependent upon an editor than upon an author. The choice of Dr. Luisada to edit the work has been fortunate. He has exhibited not only a natural talent for this task but also the quality of persevering in the face of difficulties. To him alone belongs the credit for bringing the encyclopedia to fruition. The present handbook must be regarded as a monument to his genius

ASHTON GRAYBIEL

2. Selection of persons with diversified knowledge (physiology, pathology, pediatrics, surgery, etc.), so that all fields may be covered by competent editors.

3. Choice of as many young scientists as possible, in order to have a high potential of enthusiasm, criticism, and working capacity.

The final product will reveal whether these directives are sound and have been followed as closely as possible.

The publication of this encyclopedia was made possible by the continued support of the American College of Cardiology through the action of its board of trustees, by generous contributions of five pharmaceutical houses, and by the warm collaboration of the McGraw-Hill Book Company, Inc., Blakiston Division.

ALDO A. LUISADA  
*Editor in Chief*

cardiology. It is likely that a four-volume, 5,000-page encyclopedia would represent the optimal size. However, practical considerations indicate a more limited approach for the first version. Therefore, a four-volume, 3,600-page size is considered for the first edition, even though gradual revision and extension over the following ten years will probably increase the size to that previously mentioned.

Several titles have been considered for this encyclopedia. The one preferred by the editor, *Encyclopedia of Cardiology*, has been discarded for fear of discouraging prospective readers. The more modest title which has been selected—*Cardiology*—emphasizes the main scope [knowledge about the heart (and vessels)] even though it has a more modest sound than the original title. The titles of the four volumes have been selected on the basis of their content.

The problem of correlation has been the rock on which many textbooks written by multiple authors have foundered. If the various parts do not follow a logical sequence; if some of them are disproportionately long or short; if some are written by obscure authors of poor talent while others are the result of the work of well-known authorities, then the whole encyclopedia has no value.

In order to obviate these possibilities, the following steps are necessary: (1) the authors selected should be among the best, (2) each should receive a carefully selected and clearly outlined job, and (3) the editors should be able to refuse, abbreviate, or send back for correction any received text. Therefore, courage, patience, and hard labor are necessary to ensure a successful literary production.

The outcome of the work depends to a large extent upon the selection of authors. Well-known authors who have left a mark in the history of cardiology are the natural choice. However, they may be reluctant to undertake a major task and, moreover, may not be able to ensure continuity on account of their age. A compromise may be represented by asking these authors to prepare the text in collaboration with one of their associates. The associate would be the natural choice for any future revision of the text. However, a different author may entirely revise a chapter at a future date.

Science is international. If a truly objective work is to be published, authors of all nationalities should be asked to contribute. The recent tremendous progress of cardiology in the North American continent may require that a majority of the authors be selected in the United States and Canada. However, numerous contributors have been selected from England, continental Europe, Mexico, South America, Africa, and Asia, so that a truly "global" representation of cardiology may result.

How much of the text should reflect generally accepted viewpoints; how much should present new ideas still awaiting confirmation? This problem cannot be solved in a general way. The viewpoint of the editor is that an intermediate position should be preferred. Texts reflecting only generally accepted views might render the entire work obsolete within a few years. On the other hand, many new viewpoints cannot withstand the test of time and are gradually discarded. Whatever the error, whether in the sense of conservatism or in that of progressivism, a loose-leaf type of work may remedy it more rapidly than any standard type of volume.

The Editorial Board has been selected with great care according to these viewpoints:

1. Inclusion of a few authorities which would help in laying down the directives of the work.

2. Selection of persons with diversified knowledge (physiology, pathology, pediatrics, surgery, etc.), so that all fields may be covered by competent editors.

3. Choice of as many young scientists as possible, in order to have a high potential of enthusiasm, criticism, and working capacity.

The final product will reveal whether these directives are sound and have been followed as closely as possible.

The publication of this encyclopedia was made possible by the continued support of the American College of Cardiology through the action of its board of trustees, by generous contributions of five pharmaceutical houses, and by the warm collaboration of the McGraw-Hill Book Company, Inc., Blakiston Division.

# Contents

## VOLUME 3: CLINICAL CARDIOLOGY

### PART 5: CARDIOVASCULAR DISEASES IN GENERAL

- 1 Classification of heart disease *Louis H. Sigler* 5-3
- 2 Prevalence and distribution of cardiovascular diseases *Louis H. Sigler* 5-8
- 3 Cardiovascular disease in the Orient *Mariano M. Alimurung* 5-22
- 4 Mechanisms of certain symptoms and signs in cardiovascular disease  
Jaundice, ascites, cyanosis, clubbing, peripheral edema, dyspnea *Blay Mola* 5-27  
Gallop rhythm, alternans *Aldo A. Luisada* 5-36

### PART 6. CONGENITAL HEART DISEASE

- 1 Etiology and pathogenesis of congenital heart disease  
*Maurice Lev and Elisabeth Karcoggia* 6-3
- 2 Pathology of congenital heart disease *Maurice Lev* 6-15
- 3 Clinical aspects of congenital heart disease  
*J. Francis Dammann, Jr* 6-36
- 4 Circulation time in congenital heart disease *William M. Hitzig* 6-81
- 5 The electrocardiogram in congenital heart disease  
*Demetrio Sodi Pallares and Mario R. Testelli* 6-85
- 6 Phonocardiography in congenital heart disease *Alexander S Nadas* 6-89
- 7 Electrokymography in congenital heart disease *Giano Magni* 6-98
- 8 Blood in congenital heart disease  
*Mario Stefanini and Franco Gobbi* 6-106
- 9 Cardiac catheterization in congenital heart disease  
*Alfred P Fishman and A. Gregory Jameson* 6-112
- 10 Rotntgenology in congenital heart disease *Mary Allen Engle* 6-133
- 11 Angiocardiography in congenital heart disease *Israel Steinberg* 6-152
- 12 Surgery of pulmonic stenosis with normal aortic root  
*C. Gordon Sell and H. William Scott, Jr.* 6-169

## PART 7: RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

|    |  |   |       |
|----|--|---|-------|
| 1  | The streptococci   | <i>Hutton D. Slade</i>                            | 7-3   |
| 2  | Pathology  | <i>C. George Tedeschi</i>                         | 7-12  |
| 3  | Clinical aspects of rheumatic fever  | <i>Antoni M. Diehl and Tom R. Hamilton</i>        | 7-28  |
| 4  | Clinical aspects of rheumatic heart disease  | <i>Daniel Routier</i>                             | 7-47  |
| 5  | The hemodynamics of valvular stenosis  | <i>Eugene Braunwald</i>                           | 7-58  |
| 6  | The hemodynamics of valvular regurgitation   | <i>Eugene Braunwald and Stanley J. Sarnoff</i>    | 7-63  |
| 7  | The electrocardiogram in rheumatic fever and rheumatic heart disease                                       | <i>Jean Lequime and J. Hanson</i>                 | 7-68  |
| 8  | Roentgenology in rheumatic fever and rheumatic heart disease   | <i>John B. Schwedel</i>                           | 7-75  |
| 9  | The phonocardiogram in rheumatic fever and rheumatic heart disease   | <i>Aldo A. Luisada and Ario B. Zilli</i>          | 7-84  |
| 10 | The low-frequency tracings of the precordium and the arterial and venous pulses in rheumatic heart disease | <i>Aldo A. Luisada and Eugenio Jona</i>           | 7-97  |
| 11 | The electrokymogram in rheumatic fever and rheumatic heart disease   | <i>Aldo A. Luisada and Olga M. Haring</i>         | 7-101 |
| 12 | Right heart catheterization in rheumatic heart disease   | <i>Richard Gorlin</i>                             | 7-104 |
| 13 | Left heart catheterization in rheumatic heart disease  | <i>Aldo A. Luisada and Chi Kong Li</i>            | 7-111 |
| 14 | Surgery of mitral stenosis   | <i>Dwight E. Harken and Warren J. Taylor</i>      | 7-11  |
| 15 | Surgery of mitral insufficiency  | <i>Henry Thomas Nichols and Charles P. Bailey</i> | 7-131 |
| 16 | Surgery of aortic stenosis   | <i>Robert P. Glover</i>                           | 7-142 |

- 17 Surgery of aortic valvular disease  
*Charles A. Hufnagel and Peter W. Conrad* 7-153
- 18 Surgery of tricuspid stenosis  
*Thomas J. O'Neill* 7-158
- 19 Disturbances in psychologic functions and neuropsychiatric complications in heart surgery  
*Misha S. Zaks* 7-162

#### PART 8: VIRAL, BACTERIAL, MYCOTIC, AND PARASITIC HEART DISEASE

- 1 Bacterial endocarditis  
*Walter Priest and Eugene Hildebrand* 8-3
- 2 Pathology of pericarditis and constrictive pericarditis  
*Ira Gore* 8-21
- 3 Clinical aspects of pericarditis and constrictive pericarditis  
*Herbert Elias and Linn J. Boyd* 8-27
- 4 Circulation times in pericardial diseases  
*William M. Hitzig* 8-52
- 5 Graphic data in pericarditis  
*Aldo A. Luisada* 8-54
- 6 Electrocardiography in pericarditis and constrictive pericarditis  
*Frederick G. Gillick* 8-56
- 7 Surgical treatment of constrictive pericarditis  
*J. Gordon Scannell* 8-59
- 8 Pathologic aspects of myocarditis  
*Otto Saphir and Albert I. Rubenstone* 8-63
- 9 Clinical and laboratory aspects of myocarditis  
*Earl N. Silber* 8-74
- 10 Echinococcus disease of the heart  
*Eduardo J. Canabal and Jorge Dighiero* 8-89
- 11 Parasitic heart diseases  
*A. Barbosa Lima and Ants Rassi* 8-100

#### PART 9: CARDIOVASCULAR SYPHILIS

- 1 Pathology of cardiovascular syphilis  
*Bernard F. Fetter* 9-3
- 2 Clinical aspects of syphilis and syphilitic heart disease  
*Jacob S. Golden* 9-9
- 3 Graphic data in aortic aneurysms  
*Aldo A. Luisada* 9-27

#### PART 10. CORONARY HEART DISEASE

- 1 Psychic factors in coronary heart disease  
*Philippe V. Cardon, Jr.* 10-3
- 2 Pathology of coronary heart disease  
*Herman T. Blumenthal* 10-8
- 3 Clinical aspects of coronary heart disease  
*Charles W. Crumpton* 10-29
- 4 Laboratory tests in coronary heart disease  
*John S. La Due* 10-58
- 5 Electrocardiography in coronary heart disease  
*Paul S. Barker* 10-64
- 6 Roentgenology and roentgen kymography in coronary heart disease  
*Robert Heim de Balsac* 10-80

|    |  |  |        |
|----|--|--|--------|
| 7  | Electrokymography and other graphic tracings in coronary heart disease | <i>Aldo A. Luisada and Aldo Jacono</i>       | 10-85  |
| 8  | Cardioplexy  | <i>Samuel A. Thompson</i>                    | 10-91  |
| 9  | Surgery of coronary heart disease                                      | <i>Arthur M. Vineberg</i>                    | 10-95  |
| 10 | The surgery of ventricular aneurysms                                   | <i>Houck E. Bolton and Charles P. Bailey</i> | 10-105 |

## PART 11: DISTURBANCES OF THE HEART RATE AND RHYTHM; EXCITABILITY AND CONDUCTION DISTURBANCES

|    |   |  |        |
|----|---|--|--------|
| 1  | Disturbances due to modified function of the sinoatrial node            | <i>Aldo A. Luisada</i>                         | 11-3   |
| 2  | Paroxysmal tachycardia  | <i>Max Holzmänn</i>                            | 11-7   |
| 3  | Extrasystoles   | <i>David Scherf</i>                            | 11-27  |
| 4  | Flutter and fibrillation  | <i>David Scherf</i>                            | 11-35  |
| 5  | Pathologic findings in disturbances of rate or rhythm                   | <i>Antonio Costa</i>                           | 11-41  |
| 6  | Sinoatrial and atrioventricular blocks                                  | <i>Samuel Bellet</i>                           | 11-45  |
| 7  | Graphic tracings in arrhythmias and atrioventricular block              | <i>Aldo A. Luisada</i>                         | 11-52  |
| 8  | Phonocardiography in arrhythmias and blocks                             | <i>Aldo Calo</i>                               | 11-55  |
| 9  | Bundle branch and intraventricular block                                |  |        |
|    | Bundle branch block, intraventricular block                             | <i>Aaron B. Benchimol and Paul Schlesinger</i> | 11-63  |
|    | Graphic data in bundle branch block                                     | <i>Aldo A. Luisada</i>                         | 11-89A |
| 10 | The Wolff-Parkinson-White syndrome and other forms of preexcitation     | <i>Eugene Lepeschkin</i>                       | 11-90  |
| 11 | Double rhythms (pararrhythmias)   | <i>Cornelio Papp</i>                           | 11-99  |
| 12 | Cardiac resuscitation by external electric stimulation and countershock | <i>Paul M. Zoll</i>                            | 11-107 |
| 13 | Clinical differentiation of cardiac arrhythmias                         | <i>Rustom Jal Vakil</i>                        | 11-115 |

# Classification of heart disease<sup>1</sup>

LOUIS H. SIGLER

Diseases of the heart occur in various forms and degrees of structural and functional abnormalities in different individuals. The underlying causes likewise vary greatly in different cases. For these reasons it is essential to have a clear classification of such diseases as to their underlying etiology, structural abnormalities, and functional derangements, as well as of the disturbances in rate and rhythm.

## ETIOLOGIC CLASSIFICATION

Disturbances and diseases of the heart may be caused by intrinsic local or general constitutional diseases and by extrinsic factors.

### Constitutional Diseases

- 1 Arteriosclerosis
- 2 Hypertension, with or without coronary atherosclerosis
- 3 Rheumatic fever
4. Disturbances of the nervous system
  - (a) Psychosomatic
  - (b) Neurocirculatory
  - (c) Reflexes from other diseased viscera
  - (d) Reflexes from vascular sensory receptor innervations (especially the carotid sinus)
- 5 Endocrine disease
  - (a) Hyperthyroidism
  - (b) Hypothyroidism

<sup>1</sup> It is obvious that any classification reflects the viewpoints of the writer. For this reason, Sigler's classifications may differ from those of the writers of subsequent clinical chapters. Considering the number of authors, no attempt to obtain a unity of concepts in this field of classification has been made. Editor.

- (c) Adrenocortical hypofunction
- (d) Hypoinsulinism
6. Blood dyscrasias
  - (a) Primary and secondary anemias
  - (b) Various leukemias
7. Metabolic diseases usually associated with arteriosclerosis
  - (a) Diabetes mellitus
  - (b) Gout
  - (c) Obesity
- 8 Pulmonary arterial hypertension
  - (a) Essential
  - (b) Secondary to severe chronic pulmonary disease
  - (c) Due to an acute massive pulmonary embolization
- 9 Neoplastic disease
  - (a) Primary
  - (b) Metastatic
  - (c) As an extension from adjacent structures
- 10 Collagen diseases
11. Congenital anomalies
  - (a) Due to maldevelopment
  - (b) Due to fetal infection in intrauterine life (rare)

### Extrinsic Factors

1. Infections
  - (a) Bacterial—various types and strains of bacteria
  - (b) Spirochetal, most frequent is syphilis
  - (c) Parasitic—(*Plasmodium malariae*, *Echinococcus*, *trichina*)
- 2 Intoxications

## 5-4 CARDIOVASCULAR DISEASES—GENERAL

(a) Drugs and chemicals—digitalis, quinidine, carbon monoxide, and others

(b) Bacterial toxins, as in diphtheria

3. Severe trauma penetrating and nonpenetrating chest or bodily injuries or severe strain—*extrinsic* (physical) or *intrinsic* (due to fluctuations in circulatory dynamics)

4. Vitamin B deficiency

It should be understood that the real underlying causes of heart diseases vary greatly and are largely unknown. Hereditary predisposition, climate, diet, strain, lack of rest, and many other factors undoubtedly play their part. Although arteriosclerosis, for instance, is considered as the cause of arteriosclerotic heart disease, the main underlying causes of arteriosclerosis itself are still shrouded in mystery. The same is true of the other most important causes.

### STRUCTURAL CLASSIFICATION

Structural diseases of the heart may be divided into the following five main groups: (1) inflammatory, (2) degenerative, (3) traumatic, (4) alteration in size and shape, (5) neoplastic. Inasmuch as the congenital diseases present certain characteristic pathologic and clinical abnormalities, that group will be dealt with separately.

*Inflammatory involvement* may affect any part of the heart, the coronary vessels, the aorta, and the pulmonary artery. It is usually not limited to one area, but some areas are more greatly involved than others. Depending upon the area of predominance of inflammation, there are:

1. Endocarditis

(a) Acute, subacute, and chronic

(b) Mural or valvular (valvulitis)

(c) Rheumatic, bacterial, nonbacterial or indeterminate, verrucose (Libman-Sacks disease)

2. Myocarditis

(a) Acute

(b) Chronic, with continuous or frequently recurring activity

3. Pericarditis

(a) Acute—fibrinous, serofibrinous, or purulent

(b) Chronic, usually tuberculous or rheumatic

4. Coronary arteritis, part of general arteritis: rheumatic, due to thromboangitis obliterans, periarteritis nodosa

5. Aortitis: syphilitic, rheumatic, bacterial

6. Pulmonary arteritis: syphilitic, rheumatic, bacterial, tuberculous, parasitic

*Degenerative lesions* may be divided into *chronic* and *acute*. Some of the former do not differ to any great extent from the end results of unresolved organized inflammatory processes and will be dealt with together.

### Chronic Degenerative Lesions

1. Atherosclerosis

(a) Coronary arteries

(b) Aorta

(c) Pulmonary artery

2. Pericardial and pleuropericardial

(a) Fibrosis

(b) Adhesions

(c) Calcification

3. Myocardial

(a) Fibrosis—patchy and diffuse, or massive and localized

(b) Aneurysm

(c) Fatty infiltration

4. Endocardial and valvular

(a) Fibrosis, with or without calcification

(b) Valvular defects—mitral stenosis and/or insufficiency, aortic stenosis and/or insufficiency, pulmonic stenosis and/or insufficiency, tricuspid stenosis and/or insufficiency

5. Scleroderma heart

### Acute Degenerative Lesions

1. Coronary subintimal hemorrhage

2. Coronary occlusion—thrombotic, non-thrombotic, and embolic

3. Myocardial ischemia and ischemic necrosis, disseminated

4. Myocardial infarction

5. Mural endocardial thrombosis, of the atrial or ventricular chambers

6. Granular, hyaline, and fatty degeneration due to toxic factors or other causes

### Traumatic Lesions

1. Penetrating lacerations of heart and vessels

2. Contusions and nonpenetrating lacerations

3. Myocardial infarction

4. Rupture of any of the valves

5. Tear of the chordae tendineae

6. Rupture of an aneurysm—cardiac, aortic, or pulmonic
7. Dissecting hematoma of the aorta (dissecting aneurysm)
8. Rupture of any of the chambers of the heart, of the aorta, or of the pulmonary artery

Alterations in the size of the heart and large vessels may consist of *hypertrophy, dilatation, and atrophy*

*Cardiac hypertrophy and/or dilatation* may affect.

1. The left or right atrium or ventricle
  2. Both atria and/or both ventricles in various proportions
- Hypertrophy and dilatation of the aortic or pulmonary arterial wall may be diffuse or sacular

*Atrophy of the heart and great vessels* may occur in some cases of senility or wasting diseases

Neoplasms of the heart may be *primary or metastatic*. Primary tumors are very rare. They may originate in the endocardium, myocardium, or pericardium as myomas, fibromas, or cysts. Metastatic tumors are somewhat more frequent.

## DISTURBANCES OF RATE AND RHYTHM

Disturbances in the heart rate and rhythm may occur in structurally normal hearts, although the severe arrhythmias usually occur in the presence of organic heart disease. Many of the disturbances may be diagnosed by physical examination, others require electrocardiographic studies for proper diagnosis.

The following classification is based on the focus of origin of the impulse in the heart.

### Disturbances in the Sinus Node

1. Sinus bradycardia
2. Sinus tachycardia
3. Sinoatrial standstill
4. Sinus arrhythmia

### Interruption of Sinus Rhythm by Ectopic Impulses, Origin May Be

1. Atrial
2. Nodal
3. Ventricular

### Displacement of the Pacemaker

1. Without tachycardia
  - (a) Nodal rhythm

- (b) Shifting or wandering pacemaker
- (c) Double pacemaker and parasystole with interference dissociation
2. With tachycardia
  - (a) Paroxysmal tachycardia (ectopic tachycardia)—atrial, nodal; ventricular; indeterminate
3. Flutter and fibrillation—atrial; ventricular

## Conduction Disturbances

1. Atrioventricular block
  - (a) Simple delay
  - (b) Delay with dropped ventricular beats (periodic block)
  - (c) Complete block
2. Bundle branch block
  - (a) Partial or incomplete
  - (b) Complete—left, right, indeterminate
3. Electrical alternans

## FUNCTIONAL CLASSIFICATION

Included here are not only the functional disturbances of the heart itself but also those of the peripheral circulation. These may be classified into four main headings. (1) myocardial, (2) failure of the coronary circulation, (3) peripheral vascular failure, and (4) failure of the cerebral circulation.

*Myocardial failure* varies in degree. It may affect the left ventricle in aortic valvular disease, mitral insufficiency, systemic hypertension, and other conditions, throwing a greater burden on that ventricle. It may affect the right ventricle in mitral stenosis, pulmonary valvular disease, and other conditions, placing a greater strain on that ventricle, or as a sequela of prolonged left ventricular failure. It may affect both ventricles in arteriosclerotic heart disease without hypertension, in prolonged severe arrhythmia, multiple rheumatic valvular diseases, and diffuse myocardial diseases.

*Failure of the coronary circulation* may be transient, induced by strain or effort in the presence of coronary atheromatosis, or it may be prolonged. The effects may be temporary or prolonged myocardial ischemia, resulting in ischemic necrosis and diffuse infarction. Acute failure in a localized area of the heart may be caused by sudden coronary occlusion or by hemodynamic factors. The result most often is myocardial infarction of the area affected.

*Peripheral vascular failure* due to any cause may be so severe as to cause

nous return to the heart is decreased due to widespread arteriocapillary dilatation and emptying of the venous system. This may result in cessation of the circulation.

*Failure of the cerebral circulation*, if not due to local causes, may be induced by *cardiac arrest* due to sinoatrial block, ventricular asystole (in atrioventricular block), ventricular fibrillation, or severe peripheral vascular failure. An occasional condition which may precipitate any of these mechanisms and result in cerebral manifestations is the *carotid sinus syndrome*.

The classification of patients as to *degree* of functional damage is based upon the reaction of any given individual to his usual activities. This depends not only upon the functional state of the heart but also upon extrinsic factors such as individual sensitivity, variations in psychologic reaction to disease, variations in subjective manifestations, and differences in work experiences and training previous to the onset of heart disease. A classification based on *reaction to physical activity* as a test of the functional capacity of the heart is, therefore, largely conjectural. Nevertheless, we may roughly divide the various degrees of functional incapacity into the following four classes, as adopted by the American Heart Association.

Class I. Patients with heart disease who can carry on normal physical activity.

Class II. Patients in whom normal physical activity brings about moderate subjective and objective disturbances.

Class III. Patients in whom less than ordinary physical activity brings about marked disturbances but who are still comfortable at rest.

Class IV. Patients in whom disturbances occur even at rest.

## **CONGENITAL CARDIOVASCULAR DISEASES**

Congenital cardiovascular diseases may be divided into three main groups: (1) acyanotic, (2) with late cyanosis (*cyanose tardive*), and (3) cyanotic.

*Acyanotic Group.* Here there is no abnormal communication between the pulmonary and systemic circulations and therefore no mixture of systemic venous and arterial blood. Many varieties of abnormalities occur in this group, the following are the most common:

1. Primary cardiac and valvular involvement
  - (a) Dextrocardia
  - (b) Aortic valvular or infundibular stenosis
  - (c) Bicuspid aortic valve
  - (d) Supernumerary aortic cusps
  - (e) Pulmonary valvular or infundibular stenosis
  - (f) Malformations of the tricuspid valve
  - (g) Congenital cardiac hypertrophy
2. Abnormalities of the aorta
  - (a) Double aortic arch
  - (b) Right aortic arch
  - (c) Coarctation of the aorta (infantile and adult types)
  - (d) Congenital aneurysm of the sinus of Valsalva
3. Primary dilatation of the pulmonary artery
4. Draining of the pulmonary veins into the right atrium or the superior vena cava

*Late Cyanosis* (*cyanose tardive*). Here there is a direct shunt or communication between the systemic venous and arterial systems. Under normal conditions, because of the greater pressure in the systemic than in the pulmonary side of the systems, the abnormal flow of blood through the defect is in a direction from the former to the latter, and therefore there is no cyanosis. Under conditions of strain or when a greater burden is placed on the right ventricle, the pressure on the venous side suddenly becomes greater than on the arterial side and the blood flow through the defect is in a direction from the venous to the arterial side, resulting in cyanosis. Abnormalities belonging to this group are:

1. Patent ductus arteriosus
2. Defects of the interatrial septum
  - (a) Marked patency of the foramen ovale
  - (b) Persistent ostium primum
  - (c) Atrial defect plus congenital or acquired mitral stenosis (*Lutembacher's syndrome*)
3. Patent interventricular septum
4. Patent aortic septum (usually in right sinus of Valsalva leading into pulmonary conus)

*Cyanotic Group.* Here there is a great variety in the form and degree of defects. In many

cases a permanent venoarterial shunt exists. In some, no such shunt is present but there is a serious congenital cardiac defect which slows the circulation and results in chronic alterations in the capillary loops in various parts of the body, most marked in the fingers and toes, producing marked *clubbing*. The pathologic alterations of the pulmonary circulation, plus the effect of shunts, plus changes of the systemic capillaries and polycythemia result in deficient oxygenation of the blood and the cyanosis

The common conditions presenting a permanent shunt are

1 Tetralogy of Fallot: a combination of interventricular septal defect, dextroposition of aorta, pulmonary valvular or infundibular stenosis, and right ventricular hypertrophy

2 Eisenmenger's complex: same as above except for the absence of pulmonary stenosis

and the occurrence of chronic lesions of the pulmonary vessels

3. *Cor triloculare biatriatum*: the heart consists of two atria and a single ventricle with transposition of the great vessels or with their origin in a rudimentary bulbus cordis; *cor triloculare biventriculosum*: there is complete absence of the interatrial septum

4. Persistent AV ostium. a combined partial interatrial and upper interventricular defect

5. Complete transposition of the great arterial vessels

6. Persistent truncus arteriosus: conditions in the cyanotic group, where a shunt plays no part, include among others:

(a) Pulmonary conus stenosis at the lower bulbar orifice

(b) Pulmonary atresia with closed interventricular septum

(c) Pulmonary and tricuspid stenosis

## 5-6 CARDIOVASCULAR DISEASES—GENERAL

nous return to the heart is decreased due to widespread arteriocapillary dilatation and emptying of the venous system. This may result in cessation of the circulation.

*Failure of the cerebral circulation*, if not due to local causes, may be induced by *cardiac arrest* due to sinoatrial block, ventricular asystole (in atrioventricular block), ventricular fibrillation, or severe peripheral vascular failure. An occasional condition which may precipitate any of these mechanisms and result in cerebral manifestations is the *carotid sinus syndrome*.

The classification of patients as to degree of functional damage is based upon the reaction of any given individual to his usual activities. This depends not only upon the functional state of the heart but also upon extrinsic factors such as individual sensitivity, variations in psychologic reaction to disease, variations in subjective manifestations, and differences in work experiences and training previous to the onset of heart disease. A classification based on reaction to *physical activity* as a test of the functional capacity of the heart is, therefore, largely conjectural. Nevertheless, we may roughly divide the various degrees of functional incapacity into the following four classes, as adopted by the American Heart Association

Class I. Patients with heart disease who can carry on normal physical activity.

Class II. Patients in whom normal physical activity brings about moderate subjective and objective disturbances

Class III. Patients in whom less than ordinary physical activity brings about marked disturbances but who are still comfortable at rest

Class IV. Patients in whom disturbances occur even at rest.

### CONGENITAL CARDIOVASCULAR DISEASES

Congenital cardiovascular diseases may be divided into three main groups: (1) acyanotic, (2) with late cyanosis (*cyanose tardive*), and (3) cyanotic.

*Acyanotic Group.* Here there is no abnormal communication between the pulmonic and systemic circulations and therefore no mixture of systemic venous and arterial blood. Many varieties of abnormalities occur in this group, the following are the most common:

1. Primary cardiac and valvular involvement
  - (a) Dextrocardia
  - (b) Aortic valvular or infundibular stenosis
  - (c) Bicuspid aortic valve
  - (d) Supernumerary aortic cusps
  - (e) Pulmonary valvular or infundibular stenosis
  - (f) Malformations of the tricuspid valve
  - (g) Congenital cardiac hypertrophy
2. Abnormalities of the aorta
  - (a) Double aortic arch
  - (b) Right aortic arch
  - (c) Coarctation of the aorta (infantile and adult types)
  - (d) Congenital aneurysm of the sinus of Valsalva
3. Primary dilatation of the pulmonary artery
4. Draining of the pulmonary veins into the right atrium or the superior vena cava

*Late Cyanosis (cyanose tardive).* Here there is a direct shunt or communication between the systemic venous and arterial systems. Under normal conditions, because of the greater pressure in the systemic than in the pulmonic side of the systems, the abnormal flow of blood through the defect is in a direction from the former to the latter, and therefore there is no cyanosis. Under conditions of strain or when a greater burden is placed on the right ventricle, the pressure on the venous side suddenly becomes greater than on the arterial side and the blood flow through the defect is in a direction from the venous to the arterial side, resulting in cyanosis. Abnormalities belonging to this group are.

1. Patent ductus arteriosus
2. Defects of the interatrial septum
  - (a) Marked patency of the foramen ovale
  - (b) Persistent ostium primum
  - (c) Atrial defect plus congenital or acquired mitral stenosis (Lutembacher's syndrome)
3. Patent interventricular septum
4. Patent aortic septum (usually in right sinus of Valsalva leading into pulmonary conus)

*Cyanotic Group.* Here there is a great variety in the form and degree of defects. In many

cases a permanent venoarterial shunt exists. In some, no such shunt is present but there is a serious congenital cardiac defect which slows the circulation and results in chronic alterations in the capillary loops in various parts of the body, most marked in the fingers and toes, producing marked clubbing. The pathologic alterations of the pulmonary circulation, plus the effect of shunts, plus changes of the systemic capillaries and polycythemia result in deficient oxygenation of the blood and the cyanosis.

The common conditions presenting a permanent shunt are.

1 Tetralogy of Fallot. a combination of interventricular septal defect, dextroposition of aorta, pulmonic valvular or infundibular stenosis, and right ventricular hypertrophy

2 Eisenmenger's complex same as above except for the absence of pulmonary stenosis

and the occurrence of chronic lesions of the pulmonary vessels

3. *Cor triloculare biatriatum*: the heart consists of two atria and a single ventricle with transposition of the great vessels or with their origin in a rudimentary bulbus cordis; *cor triloculare biventriculosum*: there is complete absence of the interatrial septum

4. Persistent AV ostium: a combined partial interatrial and upper interventricular defect

5. Complete transposition of the great arterial vessels

6. Persistent truncus arteriosus: conditions in the cyanotic group, where a shunt plays no part, include among others:

(a) Pulmonary conus stenosis at the lower bulbar orifice

(b) Pulmonary atresia with closed interventricular septum

(c) Pulmonary and tricuspid stenosis

# Prevalence and distribution of cardiovascular diseases

LOUIS H. SIGLER

Cardiovascular diseases are the most frequent causes of death and disability. Certain factors such as sex, age, race, and geographic location, which modify the death rates from such diseases, will be discussed in this chapter

## CAUSES OF DEATH, CONTINENTAL UNITED STATES

In Table 5-1 and Fig. 5-1 is a summary of the total number of deaths and death rate per

100,000 of the population from all causes, broken up into cardiovascular-renal and other leading diseases in the continental United States in 1950. The cardiovascular-renal group does not include fetal deaths or deaths from syphilis and diabetes, many of which were undoubtedly associated with cardiovascular disease. These would add materially to the total number of cardiovascular deaths.

It will be noted from these figures that

TABLE 5-1. DEATHS FROM MAJOR CARDIOVASCULAR-RENAL DISEASES COMPARED WITH OTHER MAJOR CAUSES, CONTINENTAL UNITED STATES, 1950

| Major causes                      | Total     | Per 100,000 population | Per cent of all major causes |
|-----------------------------------|-----------|------------------------|------------------------------|
| All causes                        | 1,452,454 | 963.8                  | 100.0                        |
| All cardiovascular-renal disease  | 778,426   | 516.0                  | 53.6                         |
| Cardiovascular disease, all forms | 753,749   | 500.2                  | 51.9                         |
| Heart disease, all forms          | 546,304   | 362.6                  | 37.6                         |
| Rheumatic                         | 22,316    | 14.8                   | 1.5                          |
| Arteriosclerotic                  | 321,003   | 213.0                  | 22.1                         |
| Hypertensive                      | 85,193    | 56.5                   | 5.9                          |
| Congenital malformation           | 8,675     | 5.8                    | 0.6                          |
| Other forms                       | 109,117   | 72.4                   | 7.5                          |
| Cerebral-vascular disease         | 156,751   | 101.0                  | 10.8                         |
| of heart disease                  | 12,563    | 8.3                    | 0.9                          |
| of heart disease                  | 30,734    | 20.4                   | 2.1                          |
| of heart disease                  | 7,397     | 4.9                    | 0.5                          |
| of heart disease                  | 21,677    | 16.4                   | 1.7                          |
| of heart disease                  | 210,733   | 139.1                  | 14.6                         |
| of heart disease                  | 81,249    | 60.6                   | 6.2                          |
| of heart disease                  | 33,959    | 22.5                   | 2.3                          |
| of heart disease                  | 25,087    | 16.7                   | 1.7                          |
| of heart disease                  | 61,810    | 43.0                   | 4.6                          |
| Other causes                      | 259,190   | 164.1                  | 17.0                         |

deaths from cardiovascular-renal diseases comprised 53.6 per cent of deaths from all causes, and deaths from cardiovascular diseases alone, 51.9 per cent. If the possible cardiovascular components of fetal deaths and deaths from syphilis and diabetes were taken into consideration, the figure would probably surpass 53.6, even if chronic nephritis and nephrosclerosis were left out, which of course have a pathologic vascular component.

It is observed that heart disease alone claimed 546,304 lives in that year, equivalent to 362.6 per 100,000 of the population or 37.6 per cent of all deaths and upward of 72 per cent of the deaths from all cardiovascular-renal diseases. Arteriosclerotic heart disease claimed the greatest number of deaths in the heart disease group, comprising 22.1 per cent of deaths from all causes and about 59 per cent of all the deaths from cardiac diseases alone.

Hypertensive heart disease was the next most frequent cause of deaths, claiming 85,193 lives, that is, 56.5 per 100,000 population or 5.9 per cent of deaths due to all causes. This comprised about 16 per cent of all heart disease deaths.

The combined deaths from arteriosclerotic and hypertensive heart disease was thus about 75 per cent of all cardiac deaths. The other 25 per cent was distributed among rheumatic and other forms of heart disease, rheumatic heart disease contributing only about 4.1 per cent.

Fig 5-1 Percentages of deaths due to various forms of cardiovascular-renal diseases compared to those caused by all other diseases, United States, 1950.

100,000 of the population, which is only 1.5 per cent of all deaths. This is a very small percentage compared with deaths caused by cardiovascular-renal diseases.

### INFLUENCE OF AGE, SEX, AND RACE

Table 5-2 is an analysis of the death rates from various forms of cardiovascular-renal diseases among males, females, whites and nonwhites, and at different ages. It will be observed that the over-all death rate for all cardiovascular-renal diseases is greater in males than in females, in both the white and nonwhite races. Also, the death rate in white males is greater than in nonwhite males. On the other hand, the death rate in nonwhite females is greater than in white females.

The various forms of cardiovascular-renal diseases show considerable differences in the death rates in whites and nonwhites, males and females. Thus, the death rates of cerebral vascular disease and hypertensive heart disease are greater in females than in males in both races and are also greater in nonwhite males than in white males. In nonwhite females, it is much greater than in white females, especially in hypertensive heart disease where the

The number of deaths from all forms of malignancies in the same year was 210,723 or 139.8 per 100,000 population, which is only 14.6 per cent of all major causes, as compared to 33.6 per cent for the cardiovascular-renal group. This is equivalent to only about 27 per cent of the percentage of deaths caused by cardiovascular-renal diseases. In other words, for every death from cancer there are about four deaths from cardiovascular-renal diseases.

It is regrettable to find that tuberculosis, infectious and contagious diseases, accidents, suicides and homicides, all of which should theoretically be preventable, still claim many lives. However, it is gratifying to find that with modern preventive measures, a comparatively small percentage of deaths is due to such causes. In 1950, the combined death rate for all these causes was only 14.8 per

**TABLE 5-2 DEATH RATES PER 100,000 POPULATION BY RACE, SEX, AGE, AND TYPE OF MAJOR CARDIOVASCULAR-RENAL DISEASE, CONTINENTAL UNITED STATES, 1950**

| <i>Cardiovascular-renal disease</i>                         | <i>Total</i> | <i>White</i> |               | <i>Nonwhite</i> |               | <i>Age</i> |             |              |              |              |                    |

| Generalized arteriosclerosis                                | 20.4         | 21.7         | 20.9          | 14.4            | 11.3          |            |             | 0.0          | 0.2          | 6.5          | 233.5              |
| Other disease of circulatory system                         | 4.9          | 5.9          | 3.9           | 5.7             | 4.7           | 0.3        | 0.2         | 0.9          | 2.0          | 8.9          | 28.0               |
| Chronic and unspecified nephritis and other renal sclerosis | 16.4         | 15.8         | 13.5          | 32.1            | 30.3          | 1.0        | 1.0         | 2.6          | 6.3          | 22.7         | 113.3              |

rate for nonwhite females is almost double that of white females. For chronic nephritis, the death rates of nonwhite males and females is more than double that of white males and females. This is also true for hypertension. On the other hand, generalized arteriosclerosis and arteriosclerotic heart disease claim a much greater number of deaths in white than nonwhite males and females, with males greatly predominating in both races.

The effect of age on the mortality rates is also very striking. The death rates for all cardiovascular-renal diseases are comparatively low up to 44 years of age. Beyond that there is a sudden increase in mortality for all forms of cardiovascular-renal diseases. The greatest rise occurs after 65 years of age.

If we compare the mortality rates from car-

diovascular-renal diseases at the various ages among white and nonwhite, males and females, we find marked differences in the various groups, as shown in Table 5-3. The death rates for all ages up to 75 years are much greater in nonwhites than in whites, and the reverse is true after that age. This means that nonwhites die younger from cardiovascular-renal diseases than do whites. It is also noted that the death rates in the younger age groups are higher in white males than females, but in nonwhites the reverse is true.

#### DEATH RATES IN VARIOUS REGIONS

Table 5-4 is an abbreviated summary of the death rates of major cardiovascular-renal diseases in various parts of the United States in 1950. It will be observed that there are marked

# PREVALENCE AND DISTRIBUTION 5-11

differences in distribution of deaths from these diseases in different regions of the country. The highest death rates appear to be in regions I and II, consisting of states where industry and commerce are the major pursuits and indoor life is most common. The lowest death rates are in regions VII and VIII, where agriculture is the predominant pursuit and open-air life is common.

Although many regions show fairly uniform death rates in the various states comprising those regions, others show considerable fluctuation in the death rates in the various states, in the same region, as shown in the list on page 5-12 and illustrated in Fig. 5-2.

## DEATH RATES IN URBAN AND RURAL AREAS

Figure 5-3 is a graphic representation of the mortality rates, from heart disease alone, in urban and rural areas in the United States and in its subdivisions in 1940. It will be observed that in the majority of States the mortality rates in urban areas were far greater than in rural regions. The average death rate from heart disease in the entire country in that year was 338.7 per 100,000 population, with a rural death rate of only 250.6. There are, however, considerable fluctuations in the urban

TABLE 5-4. AVERAGE DEATH RATES PER 100,000 POPULATION FOR MAJOR CARDIOVASCULAR-RENAL DISEASES IN VARIOUS REGIONS, CONTINENTAL UNITED STATES, 1950

| Region        | Cardiovascular-renal disease | Cardiovascular diseases | Cerebrovascular disease | Heart disease |
|---------------|------------------------------|-------------------------|-------------------------|---------------|
| I             | 593.6                        | 579.5                   | 113.9                   | 425.3         |
| II            | 589.7                        | 574.2                   | 97.9                    | 411.0         |
| III           | 453.2                        | 434.7                   | 99.2                    | 305.8         |
| IV            | 428.1                        | 406.1                   | 108.9                   | 271.3         |

TABLE 5-3. DEATH RATES PER 100,000 POPULATION FOR MAJOR CARDIOVASCULAR-RENAL DISEASES BY AGE, RACE, AND SEX, CONTINENTAL UNITED STATES, 1950

| Age                            | White    |          | Nonwhite |         |
|--------------------------------|----------|----------|----------|---------|
|                                | Male     | Female   | Male     | Female  |
| All ages                       | 585.0    | 439.4    | 528.4    | 468.8   |
| Under 5                        | 5.4      | 3.9      | 10.1     | 8.7     |
| 5-14                           | 4.7      | 5.3      | 7.9      | 10.5    |
| 15-24                          | 12.2     | 11.0     | 26.3     | 29.6    |
| 25-34                          | 31.0     | 22.0     | 79.0     | 89.6    |
| 35-44                          | 134.6    | 65.5     | 294.1    | 311.1   |
| 45-54                          | 508.1    | 217.3    | 902.6    | 802.5   |
| 55-64                          | 1,337.3  | 664.5    | 2,115.9  | 1,933.7 |
| 65-74                          | 3,091.8  | 2,053.3  | 3,280.4  | 2,692.8 |
| 75-84                          | 7,231.5  | 6,038.5  | 5,912.4  | 4,985.4 |
| 85 and over, including unknown | 15,969.9 | 14,561.8 | 10,842.1 | 9,327.3 |

and rural death rates in different parts of the country.

In some states, as in Arizona for instance, the differences were very marked, the urban death rate having been 374.6 and the rural rate only 136.5 per 100,000 population. In others, as in the East North Central states and in the New England states, the urban and rural rates approximately approach each other, in the Middle Atlantic states, the rural actually surpassed the urban rate.

## TRENDS IN MORTALITY

The mortality from cardiovascular-renal diseases has progressively increased since 1900 when the Bureau of Census first began an annual collection of mortality statistics of various

**MORTALITY RATES FROM CARDIOVASCULAR-RENAL DISEASE IN VARIOUS STATES, 1950**

|                      |       |                    |       |
|----------------------|-------|--------------------|-------|
| <i>Region I</i>      |       | <i>Region VI</i>   |       |
| Connecticut          | 541.4 | Iowa               | 578.8 |
| Maine                | 603.4 | Kansas             | 555.8 |
| Massachusetts        | 601.0 | Minnesota          | 510.6 |
| New Hampshire        | 673.4 | Missouri           | 600.1 |
| Rhode Island         | 586.6 | Nebraska           | 498.7 |
| Vermont              | 620.0 | North Dakota       | 419.4 |
|                      |       | South Dakota       | 453.3 |

| West Virginia        | 415.3 |                    |       |
| <i>Region IV</i>     |       | <i>Region IX</i>   |       |
| Alabama              | 405.8 | Arizona            | 304.3 |
| Florida              | 475.3 | California         | 503.2 |
| Georgia              | 434.0 | Nevada             | 452.9 |
| Mississippi          | 415.4 | Oregon             | 486.2 |
| South Carolina       | 414.9 | Washington         | 503.0 |
| Tennessee            | 420.0 |                    |       |
| <i>Region V</i>      |       |                    |       |
| Illinois             | 599.3 |                    |       |
| Indiana              | 574.3 |                    |       |
| Michigan             | 470.8 |                    |       |
| Ohio                 | 548.6 |                    |       |
| Wisconsin            | 553.0 |                    |       |

diseases. This increase has been most evident in heart disease. In other circulatory diseases such as cerebral vascular disease, general arteriosclerosis, and hypertension, the increase was relatively small, spotty, and fluctuating. This is shown in Table 5-5.

The marked progressive increase in heart disease during the first half of the twentieth century may partly be apparent, rather than actual. Factors that may play a part are better diagnostic acumen on the part of physicians, adoption of clearer certification of causes of death; a progressive increase in the number of states that have contributed to the statistical studies over the years; a greater shift of the population to urban life, and a general increase in longevity due to improved sanitation, the use of antibiotics, and the marked decrease in

communicable diseases, resulting in greater aging of the population which contributes most to the deaths from heart disease (Table 5-3). However, allowing for all these possibilities, some of which have been statistically adjusted, there is still an actual increase. This is true especially since 1930, when all states have been contributing to the recordings of mortalities caused by various diseases and since which time other factors mentioned above have been rather stationary.

In evaluating the statistical findings in heart disease, it is important to note that, up to 1929, diseases of the coronary arteries were classified under the heading of "diseases of the arteries." Since 1929, following the revision of the International List, coronary artery disease and "angina pectoris" were placed under the sub-

divisions of heart disease. It is the increase in the prevalence of coronary disease which is greatly responsible for the progressive rise in the mortality from heart disease. This increase appears to be actual.

The importance of coronary atherosclerosis and of hypertension as factors in the progressive increase of deaths from heart disease over these years is evidenced by the variation in the mortality rates from heart disease in the various age groups over these years (Fig 5-4). In the younger groups up to about 35 years of age, there has been a progressive decline in the mortality rate from heart disease during the years between 1900 and 1945, reaching almost a straight curve between 35 and 44 years of age. Above 45 years, however, there is a steady climb in the mortality rates in the same period. The steady fall in the mortality rates up to 35 years evidently reflects the progressive decrease in the incidence of heart disease due to infections and infectious diseases, particularly rheumatic fever. The steady rise in the mortality rates above 35 years of age is evidently due to progressive increase in the incidence of arteriosclerosis and hypertension, partly associated with increased aging of the population.

Fig. 5-3. Death rate per 100,000 population in the various geographical subdivisions, United States, 1940, urban and rural districts compared. (Sigler. Cardiovascular Disease Grune & Stratton, 1949.)

**Seasonal Variability in Mortality.** There is considerable seasonal variability in the mortality from all forms of heart diseases. The lowest rates occur in May, June, and July; mortality rises slightly in August and September and more abruptly in October and November, reaching the highest points in December and

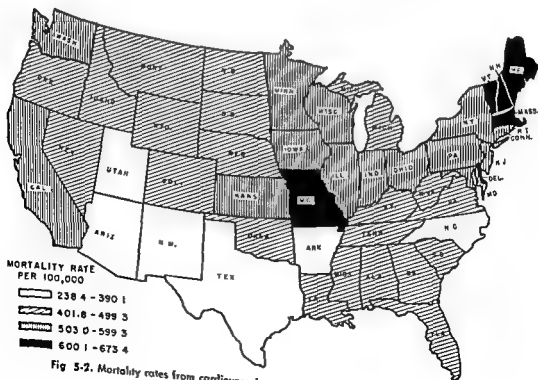

Fig 5-2. Mortality rates from cardiovascular-renal diseases in the various states, 1950.

TABLE 5-5 CRUDE DEATH RATES PER 100,000 POPULATION FOR CARDIOVASCULAR-RENAL DISEASE, REGISTRATION STATES, YEARS 1900-1950

| Year | All causes | Heart disease |      | Cerebral vascular |      | Arteriosclerosis |     | High blood pressure |      | Chronic nephritis |     |
|------|------------|---------------|------|-------------------|------|------------------|-----|---------------------|------|-------------------|-----|
|      |            | No.           | %    | No.               | %    | No.              | %   | No.                 | %    | No.               | %   |
| 1900 | 1,719.1    | 137.4         | 7.9  | 106.9             | 6.2  |                  |     |                     |      | 88.6              | 5.1 |

| 1910 | 1,468.9    | 158.9         | 10.8 | 95.8              | 6.5  |                  |     |                     |      | 94.8              | 6.3 |
| 1915 | 1,317.6    | 163.9         | 12.4 | 91.5              | 7.2  |                  |     |                     |      | 101.5             | 7.7 |
| 1920 | 1,208.9    | 159.6         | 12.2 | 93.0              | 7.2  |                  |     |                     |      | 88.8              | 6.8 |
| 1925 | 1,168.1    | 184.6         | 15.9 | 89.5              | 7.7  |                  |     |                     |      | 95.0              | 8.1 |
| 1930 | 1,132.1    | 214.5         | 18.1 | 89.0              | 7.9  | 18.5             | 1.6 | 0.4                 | 0.03 | 91.0              | 8.0 |
| 1935 | 1,094.5    | 245.4         | 22.4 | 85.7              | 7.8  | 16.9             | 1.5 | 0.6                 | 0.03 | 81.3              | 7.4 |
| 1940 | 1,074.1    | 291.9         | 27.1 | 90.8              | 8.5  | 17.2             | 1.6 | 1.0                 | 0.09 | 81.4              | 7.6 |
| 1945 | 1,062.1    | 321.6         | 30.2 | 97.9              | 9.2  | 19.7             | 1.9 | 1.4                 | 0.13 | 66.7              | 6.3 |
| 1950 | 963.8      | 362.6         | 37.6 | 101.0             | 10.8 | 20.4             | 2.1 | 8.3                 | 0.86 | 10.4              | 1.7 |

Fig. 5-4. Age-specific death rates for all forms of heart disease, on logarithmic scale, death registration, United States, 1900 to 1945. (Courtesy of Drs. Woolsey and Moriyo and the Editor of Public Health Reports, Dept. of Health, Education and Welfare, P.H.S.)

January. The lowest rate of 4 per cent is in July, while the highest of 11.5 per cent is in December. There is a somewhat greater seasonal variability in females than in males. Individuals under 20 years of age show the least variability, those over 45, the greatest.

### ILLNESS FROM CARDIOVASCULAR-RENAL DISEASES

Our knowledge of the incidence of illness from cardiovascular-renal diseases is comparatively meager because these diseases are not reportable. However, some idea of the prevalence of such diseases may be had from a survey made by the U.S. Public Health Service 1935-1936, with a house-to-house investigation in 83 cities and towns of 18 states. It embraced 700,000 households and a population of 2,500,000. Based on the results of this survey, and calculated on the basis of the 1949 census of population (149,200,000), it was estimated that, in the United States, about 9,200,000 persons are afflicted with cardiovascular-renal disease alone, 4,500,000 from arteriosclerosis alone, and 950,000 from chronic nephritis. With today's census of over 165,000,000 and with the increase in the prevalence of these diseases which has occurred in recent years, the incidence of cardiovascular diseases should be above 11 million and that of heart disease alone about 4 million. Even these figures are most likely an underestimation of the real facts.

because they refer only to diagnosed cases of cardiovascular-renal diseases. There is undoubtedly a great number of cases which are undiagnosed and are not included in the available surveys.

**Duration of Illness.** Inasmuch as the time of onset of the cardiovascular-renal diseases under investigation naturally varied widely in different individuals, the average duration of illness cannot be definitely determined. In general, however, the average duration of illness, from the time it was first diagnosed or the first symptoms appeared to the day of the investigation, was 7.7 years for heart disease, 5.5 years for hypertension, and 6.4 years for nephritis. The average for the entire group was 6.8 years. The distribution of cases according to total duration of illness in years since symptoms were first noticed or the disease was first diagnosed for all investigated cases of cardiovascular-renal diseases was as follows: less than 1 year of illness, 17.8 per cent; 1 to 2 years, 23.0 per cent; 3 to 4 years, 16.3 per cent; 5 to 9 years, 20.5 per cent; 10 to 14 years, 10.5 per cent; 15 to 19 years, 5.6 per cent; and over 20 years 6.4 per cent. All these cases included both disabling and nondisabling cardiovascular-renal diseases.

#### DISABILITY FROM CARDIOVASCULAR-RENAL DISEASES

Illness from cardiovascular-renal diseases is not always associated with disability. Many individuals can carry on a considerable degree of activity. Others may even carry on normal activity. A good many, however, may have greater or lesser disability for various periods during their lifetime.

Sufficient data are not available as to the exact extent of disability from these diseases.

From an analysis of limited series of cases cited above, we find that the rate of illness from these diseases for both sexes was about 3,769 per 100,000 population. Of these, 418 per 100,000 population (or about 11 per cent) required some restriction of activity and 1,898 were totally disabled for 7 days or longer. The entire disability rate was thus 55 per cent. Based on our present census of about 165,000,000 population with an estimated number of 11,000,000 persons suffering from cardiovascular-renal diseases, the economic effect

of such an army of disability can be readily appreciated. The rate of disability was found to be greater in females than in males.

In the same series of cases studied, the disability rates fluctuated in different age groups up to about 30 years of age, beyond that there was a steady and progressive rise in disability rate. Thus, under 5 years of age it was 67.2 per 100,000 population, between 5 and 9 years, 121.6; 10 and 14 years, 120.7; 15 to 19 years, 108.0; 20 to 24 years, 148.8; and 25 to 29, 183.8 per 100,000. Beyond 30 years of age, the rise was steady and progressive in each decade, reaching the highest increase at 85 years and over, where the disability rate was 2,811 per 100,000 living population.

An interesting fact brought out in the survey was that the rate of disability had a relationship to the economic status of the patient. Thus, families on relief showed a rate of disability which was 2.7 times greater than that of families with income of \$3,000 or more per year, and families with income of less than \$1,000 per year showed a disability rate which was 1.6 times greater than that of families with \$3,000 or more per year. These differences are probably due to loss of income caused by disease, the hard type of labor in which the poor classes are usually engaged, inability to obtain a less exacting type of work because of lack of training or education, or a combination of these factors.

The duration of disability varied markedly in different individuals. The mean for all cases with disability of 7 days or longer for both sexes and ages was 136 days for heart disease and approximately the same for all cardiovascular-renal diseases. For those cases where disability developed within the year, the mean was 70 days, while in those where disability developed prior to the year, the mean was 295 days.

**Confinement to Bed.** The mean days spent in bed by disabled cases is naturally less than the mean days of disability. There is no marked difference in this respect between males and females. However, patients below 20 years of age have longer mean days stay in bed than the older age groups. This is undoubtedly due to the fact that most cases of cardiovascular-renal diseases in the younger age groups are rheumatic and require more prolonged bed rest.

The percentage of disabled persons requiring bed treatment for one or more days during 1949 was 84 to 88 per cent for the various forms of cardiovascular-renal disease. With an estimated

## 5-16 CARDIOVASCULAR DISEASES—GENERAL

6,050,000 cases of disability from these diseases, today it would mean that 5,082,000 to 5,424,000 patients would require such treatment. However, of these, only 20 to 26 per cent were treated in hospitals for one or more days. This would imply that 1,016,400 to 1,410,240 patients with cardiovascular-renal diseases are at present being treated in hospitals one or more days during the year. The average stay in the hospital in that survey was 30 to 34 days in the various cardiovascular-renal diseases where the onset of disability was within the year studied. Where the disability developed prior to the study year, the average stay was 55 to 64 days for the different forms of cardiovascular diseases. These figures give an approximate idea of the enormity of the problem and the tremendous expense involved in handling these cases.

### HEART DISEASE IN CHILDREN AND ADOLESCENTS

As mentioned before, the mortality rates from heart disease in children and adolescents has shown a progressive decrease within the past three decades. This is due mainly to some control of rheumatic fever, which constitutes the major cause of heart disease in early life.

The actual number of cases of heart disease in these age groups in the United States is not definitely known. Recent estimates of the number of cases of rheumatic heart disease alone, in this country, are from one-half million to more than one million. Such estimates are based on a study of the frequency of occurrence of rheumatic heart disease in various populations of school children in different parts of the country.

In the few reported surveys covering only about 33,827 school children, there was a marked difference in the frequency of its occurrence in different states and even in the same state in different locations. The figures ran between 38 and 46.4 per 1,000 children examined.

More information was obtained from a survey of selective service registrants reported from various local boards and induction stations of the armed services in the United States, covering 3,317,441 men. It was found that 10 to 18 per 1,000 registrants were rejected because of the presence of rheumatic heart disease. Another survey covering examination of 4,500,000 selective service registrants revealed that over 300,000 (or about 6.7 per cent) were rejected because of structural or functional heart defects. The proportion of rejections due to rheumatic heart disease in this series was 28.4 per 1,000, or 2.84 per cent. This would

leave approximately 39 per cent of rejections due to other cardiovascular diseases or disturbances.

The incidence of congenital malformation of the cardiovascular system is also not definitely known. Judging from the mortality from congenital cardiovascular disease in 1950 (8,675) and assuming that, for every death, there are 15 still alive, the incidence would probably be in the neighborhood of 130,125. This is merely conjectural because many individuals with serious congenital diseases live less than 15 years, while there are mild forms of congenital defects which are not diagnosed. The Crippled Children Program alone has cared for 4,382 cases of congenital cardiovascular disease in 1953.

### HEART DISEASE IN PREGNANCY

The frequency of heart disease in pregnant women is not great. In 76,125 pregnant women in the Boston Lying-in Hospital during a period of twenty-five years, 1,335 or 1.8 per cent had heart disease. Of these, 1,244 or 93.0 per cent had chronic rheumatic heart disease, 69 or 5.2 per cent had congenital heart disease, and 22 or 1.8 per cent had miscellaneous forms of cardiovascular disease such as syphilitic, thyrotoxic, infectious, and others. The maternal death rate for the cardiac patients was 39 per cent. This death rate, however, had contributed 14 to 28 per cent of all maternal deaths in the various years.

In a series of 26,628 pregnancies in the Philadelphia Lying-in Division of the Pennsylvania Hospital, 409 or 1.5 per cent had heart disease. In this group, 324 or about 79.4 per cent were rheumatic, 51 or 12.5 per cent hypertensive, and 18 or 4.4 per cent congenital. The rest had miscellaneous forms, one of which was coronary artery occlusion. The functional classification consisted of 206 belonging to Class I, 143 to Class II, 46 to Class III, and 14 to Class IV. Of the entire series of 26,628 cases, 46 patients died, with a maternal mortality from all causes of 0.17 per cent. Of these 46 deaths, 14 belonged to the cardiac group, giving a mortality rate of 3.4 per cent. In other words, cardiac disease contributed 20 per cent of all maternal deaths in this series.

Reports from other large medical centers show about the same incidences of cardiac disease in pregnant women, with a great preponderance of the rheumatic group. It is thus seen that, although the incidence of heart disease in pregnancy is not great, it is an important factor in increasing the mortality rate.

## DETECTION OF EARLY CARDIOVASCULAR DISEASES

An important method of discovering early cardiovascular diseases would be screening of the general population. To date, very little has been done in that respect. The examination of selective service registrants, mentioned before, helped discover many unsuspected cases of heart disease and yielded considerable knowledge of the incidence of heart disease in the general population.

Recently, attempts have been made in a few large cities to screen the general population for cardiovascular diseases. The methods employed in some areas were the use of roentgenologic and electrocardiographic examinations. In other areas more complete examinations were made, including history taking, auscultation, and blood pressure determinations in addition to roentgenologic and electrocardiographic studies. Of 27,724 presumably normal individuals so screened, 4,783 or a little over 17 per cent have been found to have actual or suspicious cardiovascular disease. More careful reexamination of these 4,783 showed that only 1,997, or upward of 7 per cent of the 27,724 original cases, actually had some form of cardiovascular disease.

Another source of uncovering the presence of cardiovascular diseases in the general population is the x-ray surveys widely conducted in recent years for the detection of tuberculosis. In 1953, over 15 million chest x-rays were taken throughout the country. Suspected presence of cardiac disease was found in 0.1 to 1.0 per cent in different parts of the country.

## CARDIOVASCULAR DISEASES IN THE WORLD

The incidence and prevalence of cardiovascular diseases in parts of the world other than in the United States appear to be less known than in this country. Some idea, however, may be had from reported mortalities. This is shown, for many countries, in Table 5-6 which gives the total deaths from all causes with the death rate per 100,000 population, the total deaths from cardiovascular diseases with their death rates, as well as the percentage of cardiovascular deaths in relation to deaths due to all other causes.

It is observed that England, Wales, Northern Ireland, Scotland, Australia, and New Zealand have the highest death rates and percentages of deaths from cardiovascular diseases. The figures nearly approach those of the United States. Next in death rates and in the percentages of deaths from such disease are Sweden, Switzerland, Denmark, Finland, the Republic of Ireland, and Canada. Austria shows a similarly high cardiovascular death rate, but the percentages of deaths in relation to deaths due to other causes is smaller. This is due to a much greater general death rate there. France, West Germany, Belgium, Norway, Italy, and Spain have lower death rates as well as lower percentages of deaths from cardiovascular diseases. The Netherlands, Portugal, Yugoslavia, and Israel are next lower in rates and percentages. Still lower are Argentina and Japan. The lowest in rates and in percentages of deaths from cardiovascular diseases are Chile, China (Taiwan), Mexico, Egypt, and the Philippines. It is interesting to observe that in Taiwan and the Philippines, with low mortality rates and percentages from cardiovascular diseases, the general mortality rates from other causes is likewise relatively low. On the other hand, in Chile, Mexico, and especially in Egypt, the general mortality rates are extremely high. This is particularly true in Egypt, where the general mortality rate in 1952 reached a figure of 2,024.3 per 100,000 population, which is the highest rate of all countries. This would indicate that the majority of the population here die from various other diseases and only relatively few die from cardiovascular diseases. Inasmuch as most of the cardiovascular diseases are degenerative and develop beyond adulthood, it means that most of the death in such countries occur in the early years of life before such diseases set in. This is evidenced by the fact that the mortality rate from arteriosclerotic heart disease in Egypt is very low, as shown in Table 5-6.

It will also be observed from Table 5-7 that arteriosclerotic heart disease and cerebral vascular disease contribute most of the deaths from cardiovascular diseases. In nearly all countries, however, arteriosclerotic heart disease is a more frequent cause of death than cerebral vascular disease. The exceptions are Portugal, Mexico, Japan, and Chile, where the

| Philippines         | 1952         | 175,952 | 852.2   | 5,464                              | 26.5  | 3.1                               |
| Japan ..            | 1953         | 772,547 | 891.1   | 182,171                            | 210.2 | 23.5                              |
| Australia           | 1953         | 80,188  | 909.6   | 38,431                             | 435.9 | 47.9                              |
| New Zealand         | 1953         | 17,009  | 884.1   | 8,552                              | 444.8 | 50.2                              |
| China (Taiwan)      | 1953         | 78,078  | 945.1   | 8,827                              | 106.8 | 11.3                              |

death rates from cerebral vascular disease are greater than from arteriosclerotic heart disease. Of these, however, only Japan definitely has a greater cerebrovascular death rate. The other three countries have a very high death rate classed as "other heart diseases," most of which might have been arteriosclerotic heart disease which was misdiagnosed.

Although arteriosclerotic heart disease is the most prevalent form of cardiovascular disease and far surpasses in death rates its next competitor cerebral vascular disease, the relative frequencies of these two diseases vary greatly in the various countries. In some countries, such as England, Wales, Northern Ireland, Scotland, the Republic of Ireland, Australia, and New Zealand, the mortality rates from both diseases are very high, although that of cerebral vas-

cular disease is much lower. On the other hand, in France, West Germany, and Austria, the death rates from cerebral vascular disease, although lower than those of arteriosclerotic heart disease, is rather high in relation to the incidence of heart disease. In fact, in West Germany, the death rate from cerebral arteriosclerosis, which is 155.9 per 100,000 population, closely approaches that of arteriosclerotic heart disease, which is only 163.3 per 100,000 population. In Switzerland, Sweden, Canada, Denmark, and Finland, the death rates from cerebral arteriosclerosis are intermediary in relation to arteriosclerotic heart disease between the two groups of countries mentioned above. In Belgium, the Netherlands, Norway, Italy, Yugoslavia, Israel, and Portugal, the death rates from arteriosclerotic heart disease is relatively

smaller. The lowest of the European group is *Portugal*, with a death rate from this disease of only 67.1 per 100,000. However, it is questionable if this actually represents the real mortality rate. A high death rate of 71.1 per 100,000 here is classified under "other heart diseases," many cases of which might have been misdiagnosed arteriosclerotic heart disease.

The mortality rates from hypertension and hypertensive heart disease in the various countries are far lower but generally have a fairly parallel relationship to the mortality rates from arteriosclerotic heart disease. Those countries which have a high death rate from arteriosclerotic heart disease also have a fairly high death rate from hypertension. This is not true of all countries.

The death rates from rheumatic heart disease vary greatly in the different countries. It

appears to be highest in *Italy*, *England*, *Wales*, and in *Taiwan*. In the last, it appears to be the outstanding cause of death from cardiovascular disease. In *West Germany*, it is lowest, contributing only 1.3 deaths per 100,000 population.

### CONCLUSIONS

From the limited statistical findings presented here, certain theoretical considerations may be proposed as to etiology of the cardiovascular diseases and some suggestions offered as to their possible control.

The extremely high death rates from these diseases, especially from arteriosclerotic heart disease, in the United States and in all other English-speaking countries in widely separated areas of the world, suggest that the ethnic origin of these peoples may play some part in the pathogenesis of these diseases. Although all

TABLE 5-7. DEATH RATES PER 100,000 POPULATION FROM DIFFERENT FORMS OF CARDIOVASCULAR DISEASE IN FOREIGN COUNTRIES

| Country             | Rheumatic heart disease | Arteriosclerotic heart disease | Hypertensive heart disease | Hypertension, no mention of heart disease | Cerebral vascular disease | Other heart diseases |
|---------------------|-------------------------|--------------------------------|----------------------------|---|---------------------------|----------------------|
| France              |                         | 209.6                          |                            | 4.7                                       | 140.4                     |                      |
| West Germany        | 1.3                     | 163.3                          | 11.4                       | 3.0                                       | 155.9                     | 24.2                 |
| Austria             | 17.9                    | 195.2                          | 8.8                        | 6.2                                       | 159.1                     | 59.6                 |
| Belgium             | 7.6                     | 111.8                          | 18.0                       | 28.7                                      | 59.6                      | 141.3                |
| Denmark             | 7.2                     | 202.2                          | 21.4                       | 3.8                                       | 121.9                     | 35.2                 |
| Finland             | 6.7                     | 191.7                          | 36.5                       | 2.7                                       | 119.3                     | 30.8                 |
| Netherlands         | 5.6                     | 147.3                          | 10.1                       | 4.7                                       | 94.4                      | 18.4                 |
| Norway              | 9.4                     | 135.3                          | 20.7                       | 5.2                                       | 123.5                     | 32.1                 |
| Sweden              | 5.9                     | 220.5                          | 20.8                       | 3.6                                       | 125.2                     | 35.2                 |

death rates from cerebral vascular disease are greater than from arteriosclerotic heart disease. Of these, however, only Japan definitely has a greater cerebrovascular death rate. The other three countries have a very high death rate classed as "other heart diseases," most of which might have been arteriosclerotic heart disease which was misdiagnosed.

Although arteriosclerotic heart disease is the most prevalent form of cardiovascular disease and far surpasses in death rates its next competitor cerebral vascular disease, the relative frequencies of these two diseases vary greatly in some countries, such as Scotland, and New Zealand, the mortality rates from both diseases are very high, although that of cerebral vas-

cular disease is much lower. On the other hand, in France, West Germany, and Austria, the death rates from cerebral vascular disease, although lower than those of arteriosclerotic heart disease, is rather high in relation to the incidence of heart disease. In fact, in West Germany, the death rate from cerebral arteriosclerosis, which is 155.9 per 100,000 population, closely approaches that of arteriosclerotic heart disease, which is only 163.3 per 100,000 population. In Switzerland, Sweden, Canada, Denmark, and Finland, the death rates from cerebral arteriosclerosis is intermediary in relation to arteriosclerotic heart disease between the two groups of countries mentioned above. In Belgium, the Netherlands, Norway, Italy, Yugoslavia, Israel, and Portugal, the death rates from arteriosclerotic heart disease is relatively

problem. There is no denying that the laboratory must play a great role in our study of these diseases, but we believe that a greater role must be played by broader studies on a statistical basis.

For immediate control of these diseases, an attempt must be made to discover their incipency in the individual case, for guidance. This is to be done by widespread screening of the population. We feel that this can be best ac-

complished by the general practitioner who is to be made conscious of the problem and is to be taught to recognize the early phases of these diseases. This means that more time must be devoted to teaching the art of clinical diagnosis and the recognition of these diseases. Unfortunately this art has of late begun to lose ground in the profession, partly because the maze of modern laboratory experimentation may seem to make clinical observation superfluous.

problem. There is no denying that the laboratory must play a great role in our study of these diseases, but we believe that a greater role must be played by broader studies on a statistical basis.

# Cardiovascular disease in the Orient

MARIANO M. ALIMURUNG

In recent years, the study of cardiovascular epidemiology has gained importance as a source of vital data, not only for the purpose of knowing the importance and distribution of heart disease in different parts of the world but also for the discovery of certain clues that may furnish important information of etiologic significance.

Paul D. White, in 1940, said.

Heart disease is a world problem, as much as is tuberculosis or dysentery or influenza, but it has not yet been investigated as such, in contrast to many of the infectious diseases which have crossed the world, especially in the form of waves

Twelve years later, following a visit to several Oriental countries including Pakistan and India, Dr. White found the confirmation to his earlier statement. He remarked,

Heart disease, without any doubt, is one of the most serious, perhaps the most threatening malady of our times, not only in the Western world but also in the East . . . Contrary to old ideas, rheumatic heart disease, hypertension, and coronary heart disease were common in those countries even though their true prevalence has been somewhat masked by the high incidence in the past of infectious disease and faulty nutrition

leaving for us of the present day the study and control of the less dramatic, more insidious and gradual, but no less fatal maladies, such as heart disease and cancer. International cooperation and world-wide study have become the matter of fact procedure in dealing with the serious infections. The pioneer work of the Rockefeller Foundation and other groups transcending national boundaries has broken the ground and shown the way. It should not then be too hard to follow their footsteps in the collection of invaluable information about the most important causes of heart disease and the incidence and severity of their effect on the heart under all sorts of conditions and in every corner of the globe. Nature has for centuries been conducting gigantic experiments as to the effects of climate, of type of work, of diet, and of local or world-wide diseases on men, women, and children of different races, that are spread out before our very eyes for us to record and to analyze, quite readily yielding information that might never be obtainable by our own experiments on man

In 1954 this world-wide impact of heart disease became more clearly demonstrated as statistical reports of the incidence of heart disease from different countries were submitted at the Second World Congress of Cardiology. Data from Oriental countries, particularly from the Far East, have been comparatively scarce in the literature. Further, there has been the erroneous impression that heart disease, at least in some of its types, does not constitute an important problem in the Orient. Hence, a proper appreciation of this important chapter of cardiovascular epidemiology is necessary, if any conclusion is to be derived from comparative analyses with data from other parts of the world.

Papers on the incidence and importance of cardiovascular diseases have appeared in Indian journals. The inaccessibility of these publications to most workers the world over has not made possible an adequate appreciation of the above data. In the Philippines, studies have so far been limited to surveys in the large general hospitals of Manila. In Japan, the survey is still

going on, and only fragmentary information is available.

### HEART DISEASE IN INDIA

Vakil (1954) presented data on heart disease in India on the basis of a 5-year study (1941-1945) during which he reviewed 30,104 patients that were admitted to the medical wards of a hospital in Bombay. The majority of the patients were from the "low-income group," mostly laborers, mill hands, and domestic servants.

In this survey, Vakil found 1,860 cases with

dence was observed in the high incidence of 24.3 per cent of the total number of cardiac patients.

Table 5-8 shows the percentage distribution of the various etiologic forms of heart disease in Vakil's series. It is seen that the leading etiologic types were the hypertensive and coronary, 33.4 per cent together, and the rheumatic, 24.7 per cent. If, however, the hypertensive were separated from the coronary cases, then rheumatic heart disease assumes the leading figure.

Of additional interest in this study were the apparent differences in the occurrence of heart disease among four large racial groups studied: Hindus, Moslems, Christians, and Parsees and Jews. First of all, Vakil observed a relatively higher incidence of heart disease among Christians, Parsees and Jews than among the Hindus. In the second place, he pointed out racial differences in the various etiologic types. This is

**TABLE 5-8. PERCENTAGE INCIDENCE OF THE VARIOUS ETIOLOGIC TYPES OF HEART DISEASE IN INDIA**

| Etiologic type            | Per cent of total |
|---------------------------|-------------------|
| Hypertensive and coronary | 33.4              |
| Rheumatic                 | 24.7              |
| Miscellaneous             | 11.3              |
| Syphilitic                | 12.0              |
| Pulmonary                 | 10.0              |
| Unknown                   | 5.6               |
| Bacterial                 | 1.1               |
| Congenital                | 1.0               |

seen in Table 5-9. Thus, whereas syphilitic heart disease is more frequent among Moslems, the hypertensive and coronary types seem more preponderant among the Christians and the group of Parsees and Jews.

Contrary to a number of previously reported studies on the low incidence of rheumatic heart disease in the tropics, Vakil's data gave support to other more recent reports showing the high incidence of this disease in various parts of Bengal, United Provinces, Punjab, Madras, Ceylon, and Bombay. In Vakil's series, there was no noticeable difference in the incidence of rheumatic heart disease between the white races and the dark races. The disease apparently was more frequent during the hotter months of the year, and there was a predomi-

... incidence was 12.9 per cent. Among those with this type of heart disease, 56.3 per cent were Moslems and only 27.9 and 12.9 per cent were Hindus and Christians, respectively. Of interest is the finding that 27.6 per cent of these patients developed aortic aneurysms;

**TABLE 5-9. PERCENTAGE DISTRIBUTION OF RACIAL GROUPS IN THE VARIOUS ETIOLOGIC TYPES OF HEART DISEASE IN INDIA**

| Group studied             | No. cases | Moslem | Hindu | Christian | Others |
|---------------------------|-----------|--------|-------|-----------|--------|
| Congenital                | 19        | 89.4   | 10.6  | 0         | 0      |
| Rheumatic                 | 461       | 71.1   | 17.2  | 8.7       | 3.0    |
| Syphilitic                | 240       | 56.3   | 27.9  | 12.9      | 2.9    |
| Hypertensive and coronary | 768       | 50.6   | 15.2  | 23.4      | 10.8   |
| Pulmonary                 | 185       | 75.3   | 12.4  | 9.1       | 3.2    |
| Bacterial                 | 20        | 75.0   | 15.0  | 5.0       | 5.0    |
| Miscellaneous and unknown | 315       | 66.4   | 16.8  | 12.6      | 1.2    |
| All heart cases           | 1,860     | 62.3   | 17.2  | 14.8      | 5.7    |
| All medical cases         | 30,104    | 70.2   | 14.9  | 12.2      | 2.7    |

these occurred 7.7 times more frequently in the thoracic aorta than in the abdominal aorta.

Vakil's report that 29 per cent of his cardiac patients had *hypertensive heart disease* was a higher rate of occurrence than previously reported in other Indian series. As it would be expected, 92.9 per cent of them were labeled essential hypertension. The highest incidence was observed in the fifth and sixth decades of life, accounting for 55 per cent of the cases. Only 6.4 per cent of them were below 30 years of age.

*Coronary heart disease*, 13.5 per cent of the cardiac patients, showed the highest incidence (35.6 per cent) in the fifth decade of life. Apparently coronary heart disease in India involves the Christians, Parsees and Jews more often than the Moslems. Vakil found 16.4 per cent of these patients below 40 years of age, 6 of whom were under 30.

*Chronic cor pulmonale* appears to be a prominent cardiac problem in India. In this survey, Vakil reported 10 per cent of his cardiac patients with this type of heart disease, 64.4 per cent being between 40 and 59 years of age. Asthma, emphysema, and chronic bronchitis were either singly or jointly responsible for 69.4 per cent of these cases. Padmavati reported similar findings in New Delhi (1956).

HEART DISEASE IN THE PHILIPPINES

The first postwar report on heart disease in the Philippines was made by Alimurung and Grajo, based on the case records of a large hospital of Manila. Subsequently, a more extensive study was done in conjunction with three other large hospitals in Manila. This study was based on 67,826 case records from the medical and pediatric service. Since one hospital series accounts for a preponderantly male population because it originates in an army hospital, the remaining data from the other three hospitals, totaling 33,662 case records, were analyzed as one composite group. As in the series of Vakil in India, this Philippine survey was on patients in the charity wards and, therefore, belonged to the low-economic group.

In this series, there were 4,304 cardiac patients, 8 per cent of the total. Of interest is the fact that this was an average derived from a consistently increasing yearly occurrence from 6.8 per cent in 1947 to 10.1 per cent in 1953. As a cause of death, heart disease was responsible for 716 deaths. This represented 14.1 per cent of all deaths and 16.6 per cent of admissions for heart disease.

Figure 5-5 shows the relative frequencies of the various etiologic types of heart disease in

Fig. 5-5. Relative frequency of different etiologic types of heart disease in the Santa Tomas University Hospital, Philippine General Hospital, and North General Hospital (in the Philippines).

this Philippine survey. In both the medical and pediatric services, rheumatic heart disease was the leading cause, accounting for 46.6 per cent in the medical group, 54.9 per cent in the pediatric group, and 47.1 per cent in the combined series. Such a high rate of occurrence of rheumatic heart disease was attributed to the frequency of streptococcal infections, further enhanced by the setback in living conditions following World War II.

Hypertension, arteriosclerosis (coronary heart disease), and *cor pulmonale* figured next in the adult cardiac patients, whereas congenital cardiac malformations were second among the children.

As in India, chronic *cor pulmonale* appears to be a relatively prominent type of heart disease in the Philippines. In the present series, 4.2 per cent of the patients had this condition. In a subsequent study covering a 9-year period (1947 to 1955), Torralba and Almorung analyzed cases of *cor pulmonale* seen in a teaching hospital and found a relative incidence of 8.6 per cent among all cardiac patients. Of these, 59 (75 per cent) were between the fourth and sixth decades of life. There were four pediatric patients, the youngest being 1 year and 7 months old. The leading types of pulmonary disease in these patients were bronchial asthma and pulmonary tuberculosis, 57 and 25 per cent, respectively.

When compared with three other series from Mexico, New England, and Texas, the data obtained in the Philippines showed some interesting differences: (1) a similar frequency of occurrence of rheumatic heart disease with that of Mexico (41 per cent) and much lower than that of the United States, (2) a higher rate of chronic *cor pulmonale* than any of these three Western series, (3) a remarkably lower rate of syphilitic heart disease, and (4) unimpressive rates for hypertension and coronary heart disease, probably higher than previously suspected.

#### HEART DISEASE IN JAPAN

The spectrum of heart disease in Japan is currently being surveyed (Machizawa). The revealing study of Kimura on 10,000 postmortem examinations at a teaching hospital is most impressive, however. This extensive study disclosed only 75 cases with myocardial infarction,

a distinctly low figure. Kimura went further and personally examined 1,007 hearts in order to study more closely coronary arteriosclerosis. He found that the incidence of severe coronary arteriosclerosis in Japan is about one-tenth of that in persons of the same age in the United States.

In searching for possible factors relating to the development of coronary sclerosis, Kimura observed the following: (1) among the males, there was no difference on the basis of the place of lifelong residence, (2) among the females, the disease occurred more frequently among city women than among country women; (3) the incidence was 20 to 50 per cent higher among the men who used alcohol and tobacco; and (4) there appeared no significant difference based on the type of work done, whether physical or mental.

From the point of view of vital statistics, Kusakawa reviewed data from 1935 to 1951 and reported an increase in the death rate from coronary heart disease over these 16 years, being 7.5 per 100,000 in 1935 and slightly less than 10 per cent in 1951. Myocardial disease likewise rose from 11 to 13 deaths per 100,000, then increased abruptly to 21 per cent in 1947, 25 in 1949, and 36 in 1951. In general, the data showed a similar pattern of increasing frequency. Kusakawa attributes this trend to either an absolute increase in frequency of heart disease or an increasing accuracy of diagnosis of heart disease in more recent years. The particularly interesting observation is the fact that the prevalence of coronary disease remains at a low level.

#### SUMMARY

The three sources of data on heart disease in the Orient—India, Philippines, and Japan—reveal that heart disease is also an important problem in these countries. Moreover, there seems to be an increasing number of cardiac patients due to either an actual increase of heart disease or an increasing accuracy in diagnosis.

Rheumatic heart disease appears as the most frequent single etiologic type.

Chronic *cor pulmonale* seems to be a comparatively important problem in the Orient. Bronchial asthma and pulmonary tuberculosis appear to be the main pulmonary diseases responsible for this cardiac condition.

Coronary heart disease has a strikingly low incidence in Japan. In India and the Philippines, this disease has not yet attained the high rate of occurrence in the United States, but it does account for approximately 15 per cent of all heart cases.

Hypertensive heart disease is also gaining ground, ranking second among the types of heart disease seen.

Syphilitic heart disease is vanishing in the Philippines, although it still occurs quite frequently in India, especially among the Moslems.

Although responsible for only 1 per cent in India, congenital cardiac malformations were seen in 6 per cent of cardiac patients in the Philippines. This is probably due to greater accuracy of diagnosis and not to an actual greater incidence.

These data prove beyond doubt that heart disease is a truly universal problem. Epidemiologic studies are therefore needed, particularly because they may yield information of great value in the search for those clues that would offer solution to many unsolved aspects of heart disease.

# Mechanisms of certain symptoms and signs in cardiovascular disease

Jaundice, Ascites, Cyanosis, Clubbing, Peripheral Edema, Dyspnea

BLAS AROIA

Gallop Rhythm; Alternans

ALDO A. LUISADA

## JAUNDICE

In spite of the marked circulatory and parenchymatous alterations of the liver in prolonged congestive failure, jaundice is not frequent in

jaundice when present is not marked, as these patients usually have a certain amount of cyanosis, the combination of both gives a characteristic yellowish-bluish color to the skin

en  
the

would support Ottenberg's hypothesis that the slight amount of bilirubin in the fluid of edema is due to the small percentage of proteins of this fluid, which cannot absorb much pigment. On the contrary, the ascitic fluid has a high concentration of protein

*Hyperbilirubinemia* in heart failure can be due to three basic mechanisms: biliary regurgitation, hepatic insufficiency, and increased production of bilirubin. Levels of both direct and indirect bilirubin can be found elevated, even though the alkaline phosphatase level is generally within normal limits or slightly elevated (Sherlock). It is evident that the increase in

amount of direct bilirubin in the blood is due to a certain degree of obstruction or biliary regurgitation. This finding has been explained as the result of a compression of the biliary capillaries by the dilated venules, brought about by the marked venous hypertension or obstruction by biliary thrombi (Eppinger), and also a disruption of the biliary capillaries produced by centrilobular hemorrhagic necrosis (Lopez Garcia et al.). Cardiac catheterization and needle biopsy of the liver disclosed a relationship between the severity of this anatomic alteration and the increased pressure in the hepatic veins (Giraud et al.).

This biliary regurgitation must play an important role in the production of jaundice in cardiac failure, but certain authors discount its value (Sherlock).

Another important cause is the inability of the hepatic cells to absorb and excrete blood bilirubin. The remarkable alterations of the hepatic parenchyma explain the altered hepatic function. As shown by biopsy, these alterations may range from simple changes in the cells surrounding the centrilobular veins to actual necrosis in areas that extend more than one-third of the radius of the lobule, possibly followed by cirrhosis (Sherlock). Alteration may be present without evident histologic changes, as a result of the oxygen deficiency caused by

Coronary heart disease has a strikingly low incidence in Japan. In India and the Philippines, this disease has not yet attained the high rate of occurrence in the United States, but it does account for approximately 15 per cent of all heart cases.

Hypertensive heart disease is also gaining ground, ranking second among the types of heart disease seen.

Syphilitic heart disease is vanishing in the Philippines, although it still occurs quite frequently in India, especially among the Moslems.

Although responsible for only 1 per cent in India, congenital cardiac malformations were seen in 6 per cent of cardiac patients in the Philippines. This is probably due to greater accuracy of diagnosis and not to an actual greater incidence.

These data prove beyond doubt that heart disease is a truly universal problem. Epidemiologic studies are therefore needed, particularly because they may yield information of great value in the search for those clues that would offer solution to many unsolved aspects of heart disease.

It is evident that as water and sodium stagnate in the abdominal cavity, the body tends to retain them, and that such retention facilitates an increase of ascitic fluid, resulting in a vicious circle. Finally, the hypoproteinemia due to constant shift of proteins into the abdominal cavity will aggravate the condition.

Although the ascitic fluid accumulated in the peritoneal cavity appears as a steady deposit, there is actually a dynamic equilibrium with the blood (Hyatt et al.) According to McKee et al., there is a complete turnover of the albumin of the ascitic fluid in about 2 days; according to Prentice et al., from 40 to 80 per cent of the total ascitic fluid is removed and replaced each hour.<sup>1</sup>

Ascites caused by constrictive pericarditis disappears after pericardiectomy, this clearly confirms the important role played by venous hypertension in its production. It is well known that prolonged cardiac failure causes liver cirrhosis. The permanent constriction of the intrahepatic veins due to chronic congestion can determine an irreversible ascites, even though the pressure of the inferior vena cava is diminished.

It is evident that all factors that favor edema in congestive failure will aggravate existing ascites.

## CYANOSIS

Cyanosis occurs when the capillary blood has more than 5 Gm/100 ml of reduced hemoglobin (Lundsgaard et al.) Each gram of hemoglobin fixes 1.33 vol oxygen. Therefore, normal blood containing 15 Gm hemoglobin per cent should fix 20 vol of oxygen. In normal human beings, the blood is not completely oxygenated in the lungs, so that it usually has about 95 per cent saturation. This could be described also by saying that if the blood leaves the lungs saturated with 19 vol oxygen, it has 5 per cent degree of unsaturation and 0.75 Gm/100 ml of reduced hemoglobin.

In passing through the tissues, the blood loses normally about 5 vol oxygen, so that the venous blood has 14 vol oxygen less than the completely saturated blood. It has consequently a 30 per cent degree of unsaturation and 4.5 Gm/100 ml of reduced hemoglobin.

It has been calculated that the quantity of hemoglobin of the capillary blood is equal to one-half the sum of the quantity of reduced hemoglobin in the arterial blood plus that of the venous blood. Consequently, in the last example, it will be

$$\frac{0.75 + 4.5}{2} = 2.6 \text{ Gm/100 ml}$$

It is easy to notice that in order to obtain 5 Gm/100 ml reduced hemoglobin in the capillary blood, the quantity of reduced hemoglobin in the arterial blood is the most important element. Let us assume that the blood leaves the lungs saturated only by 75 per cent, i.e., that it lacks 5 vol oxygen in order to be completely saturated and has 3.75 Gm/100 ml reduced hemoglobin. It will lose, as usual, 5 vol oxygen in passing through the tissues, so that the venous blood will have a drop of 10 vol oxygen from the original level and has consequently 7.5 Gm/100 ml reduced hemoglobin. The capillary blood will have, then,  $(3.75 + 7.5)/2 = 5.62$  Gm/100 ml reduced hemoglobin, i.e., enough to produce cyanosis.

Let us suppose instead that the blood leaves the lungs with a normal saturation (95 per cent) but, in its course through the tissues, loses 10 vol oxygen per cent instead of 5, then, it will have 7.5 Gm/100 ml reduced hemoglobin, and the capillary blood will have  $(0.75 + 7.5)/2 = 4.12$  Gm/100 ml reduced hemoglobin, or not enough to cause clinical cyanosis.

Unsaturation of the arterial blood may be due to altered blood circulation of the lungs or its mixture with venous blood through a shunt. Cyanosis occurring because of this mechanism is called *central cyanosis*.

Unsaturation of the venous blood is seen in slowing of the peripheral circulation (so-called "stasis") like that caused by heart failure (congestive failure). Cyanosis of this type is called *peripheral cyanosis*. It occurs only in advanced heart failure with marked decrease of cardiac output and very slow peripheral circulation. This mechanism, however, often increases the cyanosis caused through another mechanism. Any factor that tends to accelerate local circulation (local warmth, massage, etc.) leads to local disappearance of the peripheral cyanosis.

Another cause of cyanosis is the mixture of poorly oxygenated (venous) blood with normally oxygenated (arterial) blood through anomalous shunts of the heart or vessels. This type of "central cyanosis" is characterized by

the disturbed hepatic circulation or the poor saturation of blood in the lungs (Keefer et al.; Rich et al.). It has been proved that in chronic cardiac failure, splanchnic blood flow may be decreased by as much as 33 per cent, so that the venous hepatic blood is even more unsaturated. It is possible that the oxygen tension of the blood is not sufficient to maintain alive all the cells while the blood flows from the periphery to the interior of the lobule.

*Hepatic failure* is accentuated if blood leaves the vessels (pulmonary infarct, severe and lasting pulmonary stasis) and there is an increase in production of bilirubin that must be excreted by the liver (Keefer et al.; Rich et al.). Although a different mechanism is involved, bilirubin can also be retained as a consequence of a marked decrease of cardiac output, then hepatic blood flow and consequently the amount of bilirubin offered to the hepatic cell to be excreted decrease and bilirubin is retained in the blood. An intramuscular injection of blood (the same amount as is destroyed in a pulmonary infarction) does not produce hyperbilirubinemia in patients with cardiac failure. Therefore, Rich and Resnik believe that the mechanism by which pulmonary infarction produces or aggravates jaundice is not the increased amount of bilirubin but a decreased oxygen saturation of the blood in the lungs. In addition, it is evident that pulmonary embolism produces a marked aggravation of cardiac failure, which further impairs liver function. Whatever the mechanism, it is clear that pulmonary infarction is not indispensable for the causation of jaundice. Consequently, with or without pulmonary infarction, jaundice in cardiac failure depends upon the structural lesions that facilitate biliary regurgitation and the functional impairment of the hepatic cells. For this reason, it is only observed in severe and lasting cardiac failure.

Certain drugs, such as chlorpromazine (Morrison et al.), methyltestosterone, etc., when administered to these patients, can also produce jaundice.

### ASCITES

Ascites is the transudation of fluid into the peritoneal cavity. It has the same meaning as hydrothorax, hydropericardium, and peripheral edema. It appears in the advanced state of right heart failure. However, certain aspects of ascites justify a discussion of its mechanism.

In constrictive pericarditis and tricuspid insufficiency, ascites may appear very early and last for a long time, even though peripheral edema is not severe. Besides, while edema fluid contains not more than 0.5 per cent of proteins, the ascitic fluid usually contains from 2 to 3 per cent. Exudates obviously would contain a higher percentage.

Ascites may be favored or caused by various factors, such as increase of portal pressure, decrease of colloid osmotic pressure of the serum, disturbance of the lymphatic circulation due to intrahepatic venous hypertension, excess of antidiuretic hormone, and disturbances of the electrolytic metabolism (Snell). However, the increased pressure of the hepatic veins has probably the greatest importance. Experimental portal hypertension usually does not cause ascites and is a stimulus to the establishment of collateral circulation. However, in man, portal obstruction due to extrahepatic alterations is at times accompanied by ascites, especially when the collateral circulation is not well developed (Baggenstoss et al.).

Ascites usually does not appear after ligation of the inferior vena cava, if this is made below the hepatic veins; on the contrary, it appears constantly if the ligation is made above the opening of these veins or if the hepatic veins are ligated (McKee et al.; Volmiller et al.). Several authors (Koback) have produced experimental ascites by this procedure. Milnes has observed that in such conditions, the ligation of the portal vein does not improve the ascites and that, on the contrary, the latter decreases spontaneously (Volmiller et al.) or following ligation of the hepatic and splenic arteries (Berman et al.). In human beings, the *veegee pressure of the hepatic veins, which seems to be similar with portal venous pressure*, was found raised in patients with cirrhosis of Laennec, especially in the presence of esophageal varicosities and jaundice, but was not related to the presence or absence of ascites (Taylor et al.).

Consequently, as suggested by Child, most of the ascitic fluid transudes from the hepatic surface and is primarily due to intrahepatic venous hypertension, which increases lymphatic flow according to hydrodynamic laws (Starling). The high concentration of albumin in the ascitic fluid is explained by the fact that the capillaries of the liver are extremely permeable to proteins (Starling).

It is evident that as water and sodium stagnate in the abdominal cavity, the body tends to retain them, and that such retention facilitates an increase of ascitic fluid, resulting in a vicious circle. Finally, the hypoproteinemias due to constant shift of proteins into the abdominal cavity will aggravate the condition.

Although the ascitic fluid accumulated in the peritoneal cavity appears as a steady deposit, there is actually a dynamic equilibrium with the blood (Hyatt et al.). According to McKee et al., there is a complete turnover of the albumin of the ascitic fluid in about 2 days; according to Prentice et al., from 40 to 80 per cent of the total ascitic fluid is removed and replaced each hour.<sup>1</sup>

Ascites caused by constrictive pericarditis disappears after pericardiectomy, this clearly confirms the important role played by venous hypertension in its production. It is well known that prolonged cardiac failure causes liver cirrhosis. The permanent constriction of the intrahepatic veins due to chronic congestion can determine an irreversible ascites, even though the pressure of the inferior vena cava is diminished.

It is evident that all factors that favor edema in congestive failure will aggravate existing ascites.

## CYANOSIS

Cyanosis occurs when the capillary blood has more than 5 Gm/100 ml of reduced hemoglobin (Lundsgaard et al.). Each gram of hemoglobin fixes 1.33 vol oxygen. Therefore, normal blood containing 15 Gm hemoglobin per cent should fix 20 vol of oxygen. In normal human beings, the blood is not completely oxygenated in the lungs, so that it usually has about 95 per cent saturation. This could be described also by saying that if the blood leaves the lungs saturated with 19 vol oxygen, it has 1 per cent degree of unsaturation and 0.75 Gm/100 ml of reduced hemoglobin.

In passing through the tissues, the blood loses normally about 5 vol oxygen, so that the venous blood has 14 vol oxygen less than the

It has been calculated that the quantity of hemoglobin of the capillary blood is equal to one-half the sum of the quantity of reduced hemoglobin in the arterial blood plus that of the venous blood. Consequently, in the last example, it will be

$$\frac{0.75 + 4.5}{2} = 2.6 \quad (\text{Gm/100 ml})$$

It is easy to notice that in order to obtain 5 Gm/100 ml reduced hemoglobin in the capillary blood, the quantity of reduced hemoglobin in the arterial blood is the most important element. Let us assume that the blood leaves the lungs saturated only by 75 per cent, i.e., that it lacks 25 vol oxygen in order to be completely saturated and has 3.75 Gm/100 ml reduced hemoglobin. It will lose, as usual, 5 vol oxygen in passing through the tissues, so that the venous blood will have a drop of 10 vol oxygen from the original level and has consequently 7.5 Gm/100 ml reduced hemoglobin. The capillary blood will have, then,  $(3.75 + 7.5)/2 = 5.62$  Gm/100 ml reduced hemoglobin, i.e., enough to produce cyanosis.

Let us suppose instead that the blood leaves the lungs with a normal saturation (95 per cent) but, in its course through the tissues, loses 10 vol oxygen per cent instead of 5, then, it will have 7.5 Gm/100 ml reduced hemoglobin, i.e., enough to cause clinical cyanosis.

Unsaturation of the arterial blood may be due to altered blood circulation of the lungs or its mixture with venous blood through a shunt. Cyanosis occurring because of this mechanism is called *central cyanosis*.

Unsaturation of the venous blood is even less

usually. Cyanosis of this type is called *peripheral cyanosis*. It occurs only in advanced heart failure with marked decrease of cardiac output and very slow peripheral circulation. This mechanism, however, often increases the cyanosis caused through another mechanism. Any factor that tends to accelerate local circulation (local warmth, massage, etc.) leads to local disappearance of the peripheral cyanosis while it does not change central cyanosis.

In congenital malformations of the heart, the fundamental cause of cyanosis is the mixture of poorly oxygenated (venous) blood with normally oxygenated (arterial) blood through anomalous shunts of the heart or vessels. This type of "central cyanosis" is characterized by

<sup>1</sup> This is confirmed by the fact that the ascitic fluid is replaced normally as an Editor.

the disturbed hepatic circulation or the poor saturation of blood in the lungs (Keefer et al.; Rich et al.). It has been proved that in chronic cardiac failure, splanchnic blood flow may be decreased by as much as 33 per cent, so that the venous hepatic blood is even more unsaturated. It is possible that the oxygen tension of the blood is not sufficient to maintain alive all the cells while the blood flows from the periphery to the interior of the lobule.

*Hepatic failure* is accentuated if blood leaves the vessels (pulmonary infarct, severe and lasting pulmonary stasis) and there is an increase in production of bilirubin that must be excreted by the liver (Keefer et al.; Rich et al.) Although a different mechanism is involved, bilirubin can also be retained as a consequence of a marked decrease of cardiac output, then hepatic blood flow and consequently the amount of bilirubin offered to the hepatic cell to be excreted decrease and bilirubin is retained in the blood. An intramuscular injection of blood (the same amount as is destroyed in a pulmonary infarction) does not produce hyperbilirubinemia in patients with cardiac failure. Therefore, Rich and Resnik believe that the mechanism by which pulmonary infarction produces or aggravates jaundice is not the increased amount of bilirubin but a decreased oxygen saturation of the blood in the lungs. In addition, it is evident that pulmonary embolism produces a marked aggravation of cardiac failure, which further impairs liver function. Whatever the mechanism, it is clear that pulmonary infarction is not indispensable for the causation of jaundice. Consequently, with or without pulmonary infarction, jaundice in cardiac failure depends upon the structural lesions that facilitate biliary regurgitation and the functional impairment of the hepatic cells. For this reason, it is only observed in severe and lasting cardiac failure.

Certain drugs, such as chlorpromazine (Morrissett et al.), methyltestosterone, etc., when administered to these patients, can also produce jaundice.

## ASCITES

Ascites is the transudation of fluid into the peritoneal cavity. It has the same meaning as hydrothorax, hydropericardium, and peripheral edema. It appears in the advanced state of right heart failure. However, certain aspects of ascites justify a discussion of its mechanism.

In constrictive pericarditis and tricuspid insufficiency, ascites may appear very early and last for a long time, even though peripheral edema is not severe. Besides, while edema fluid contains not more than 0.5 per cent of proteins, the ascitic fluid usually contains from 2 to 3 per cent. Exudates obviously would contain a higher percentage.

Ascites may be favored or caused by various factors, such as increase of portal pressure, decrease of colloid osmotic pressure of the serum, disturbance of the lymphatic circulation due to intrahepatic venous hypertension, excess of antidiuretic hormone, and disturbances of the electrolytic metabolism (Snell). However, the increased pressure of the hepatic veins has probably the greatest importance. Experimental portal hypertension usually does not cause ascites and is a stimulus to the establishment of collateral circulation. However, in man, portal obstruction due to extrahepatic alterations is at times accompanied by ascites, especially when the collateral circulation is not well developed (Baggenstoss et al.).

Ascites usually does not appear after ligation of the inferior vena cava, if this is made below the hepatic veins, on the contrary, it appears constantly if the ligation is made above the opening of these veins or if the hepatic veins are ligated (McKee et al.; Vollmiller et al.). Several authors (Koback) have produced experimental ascites by this procedure. Milnes has observed that in such conditions, the ligation of the portal vein does not improve the ascites and that, on the contrary, the latter decreases spontaneously (Vollmiller et al.) or following ligation of the hepatic and splenic arteries (Berman et al.). In human beings, the wedge pressure of the hepatic veins, which seems to be similar with portal venous pressure, was found raised in patients with cirrhosis of Laennec, especially in the presence of esophageal varicosities and jaundice, but was not related to the presence or absence of ascites (Taylor et al.).

Consequently, as suggested by Child, most of the ascitic fluid transudes from the hepatic surface and is primarily due to intrahepatic venous hypertension, which increases lymphatic flow according to hydrodynamic laws (Starling). The high concentration of albumin in the ascitic fluid is explained by the fact that the capillaries of the liver are extremely permeable to proteins (Starling).

The widening and deformation of the distal portions of the fingers and toes are fundamentally due to increased volume and thickness of the soft tissues, accompanied by changes in the nails ("glass watch nails"), which sometimes become a prominent feature. The skin of these parts is unusually warm.

In general, hypertrophy of the phalanges is observed only in advanced clubbing and does not contribute to this process. In children, the growing of the soft tissues can be of such magnitude as to determine an atrophy of the phalax through compression (Weens et al.).

The hyperemia and edema of these areas explain why clubbing may occasionally appear in acute form (McCord et al.) and may also disappear, if its cause is removed. A typical example is observed in bacterial endocarditis: as soon as the antibiotic treatment is able to control the infection, one can observe a groove that clearly limits the curved distal part of the nail from the normally growing proximal part.

The ossifying periosteal lesions are usually seen early and with predominance in the distal parts of the radius, cubitus, tibia, and fibula. They have a tendency to progress toward the proximal portion of these bones but do not usually involve the joints (Gall et al.). In the most advanced cases, the metacarpal and metatarsal bones (rarely the phalanges) may become involved (Gall et al.). In some cases, lesions of the scapula, patella, iliac crest, nose, or zygomatic process have been observed (Kessel et al.; Paterson). Although this process is usually bilateral and symmetrical, it may predominate in one or the other section.

The periosteal inflammation is characterized by infiltration of lymphocytes and plasma cells. It produces a "pseudocortex," with the formation of a new subperiosteal bone that finally becomes united with the original bone cortex and thickens it (Gall et al.).

The joints may present chronic synovitis and degenerative changes of the cartilage, which are not specific for clubbing. This explains why patients sometimes complain of pain in the limbs (Gall et al.).

The above changes are commonly observed in various cardiac and pulmonary diseases, especially in those that are accompanied by cyanosis. They may also be found in diseases of other systems (pyelonephritis, ulcerative colitis, bacillary dysentery, regional enteritis,

sprue, biliary cirrhosis, chronic intoxications, etc.) (Carr; Locke, Mendlowitz).

There also is a congenital form of clubbing, which appears with familial character in healthy persons. This type of alteration is easily recognized because it is not accompanied by periosteal inflammation and because the soft tissues on the sides of the nails maintain their normal form.

The mechanism responsible for clubbing and its associated lesions is still controversial (Mendlowitz). In most cases, the change could be due to increased blood flow in the limbs, but this does not apply to the congenital form. An increase of blood flow may be caused in part by a higher digital arterial pressure. In a case of pulmonary abscess, the remission of clubbing coincided with the normalization of flow and digital arterial pressure due to surgical removal of the abscess. In other chronic inflammatory processes, not accompanied by clubbing, the digital blood flow seems to be normal (Mendlowitz).

The fact that when clubbing is associated with hypertrophic osteopathy, digital circulation is not increased, might be interpreted as being due to a stabilization of the phenomenon in the fingertips while increased blood flow still occurs in the bones (Mendlowitz).

In cyanotic congenital heart diseases, the severe dilatation of the capillaries and venules, with the corresponding stasis of blood rich in hemoglobin and red cells, might be a possible factor (Redisch et al.).

The toxic, infectious factor may be responsible for clubbing in certain cases (e.g., in bacterial endocarditis—when the infection is treated, clubbing disappears). However, there is probably an indirect connection, because many other chronic infections do not cause clubbing. The possible intervention of neurogenic (Locke) or endocrine factors (Fried) has been advocated. It would be logical to admit that when certain infectious or degenerative processes are localized in certain organs or tissues, they produce substances which, through an unknown mechanism, accelerate blood flow in the fingertips and thus originate clubbing.

The hypoxic blood would act in the same way, as in congenital malformations of the heart, respiratory diseases with alveolar hypoventilation, etc. According to Levy et al., clubbing is always connected with anoxemia. Mauer

decreased oxygen saturation of the arterial blood while that of the pulmonary veins is normal. It is obvious that the mixture occurs after the entrance of the pulmonary blood in the left atrium.

When there is a functional cause of poor oxygen intake in the lungs (low pressure of the atmosphere—high altitude) or an organic cause (pulmonary disease), the blood cannot be properly oxygenated during its passage through the pulmonary capillaries. A similar disturbance occurs in a pulmonary arteriovenous fistula which permits a bypass of the capillaries of the lungs (Moia et al.). In all these cases, there is another type of *central cyanosis*, in which both the arterial blood and that of the pulmonary veins present a low oxygen saturation.

When there is either a functional or an organic disturbance of the oxygen intake in the lungs, inhalation of 100 per cent oxygen decreases the cyanosis. This test has been suggested as a simple method for differentiating central cyanosis caused by pulmonary diseases from central cyanosis caused by right-to-left shunt. However, cyanosis may decrease somewhat also in the latter cases (Montgomery et al.), although very slowly (Gullickson et al.). The change is due not to a pulmonary factor of anoxemia but to the fact that during inhalation of pure oxygen, this gas dissolves in plasma (up to 2 vol/100 ml) (Selzer), thus contributing to the oxygenation of reduced hemoglobin in the venous blood.

The diminution of pulmonary flow, as observed in severe pulmonic stenosis, probably also plays a role in causing cyanosis of certain congenital malformations of the heart (Taussig and Blalock).

Even though anastomosis of one peripheral artery with a branch of the pulmonary artery, proposed by Blalock and Taussig in order to increase this inadequate pulmonary circulation, markedly improves cyanosis in certain congenital malformations of the heart, the mechanism causing the change is still under debate. In fact, *isolated pulmonary stenosis does not cause cyanosis*. When there is cyanosis, it is due to the concomitant existence of a right-to-left shunt.

Selzer points out that in a similar case, there was, before surgery, a 2-liter shunt and a 2-liter flow through the lungs. After the operation, pulmonary flow was increased from 2 to 4 liters and

consequently the systemic flow was increased from 4 to 6 liters. As 2 liters of the increased systemic flow went from the systemic to the pulmonary system, the venous return to the right ventricle would not be changed but pulmonary flow would be twice as large as before. The 2 liters of venous blood that were shunted were mixed with 4 liters of arterial blood instead of with 2 liters, and the percentage of concentration of the reduced hemoglobin was proportionally decreased. This explains the disappearance or attenuation of the cyanosis.

As a result, the Blalock-Taussig operation is not a specific treatment for either Fallot's tetralogy or pulmonic stenosis. All conditions in which venous and arterial blood are mixed before entering the systemic circulation can benefit by it, because the proportion of oxygenated blood is increased. Cyanosis improves not because of an increased amount of oxyhemoglobin but because of a decreased concentration of reduced hemoglobin. It is necessary to keep in mind that cyanosis is related not to the greater or lesser quantity of oxyhemoglobin but to the absolute concentration of reduced hemoglobin and, therefore, is not dependent upon the relationship between reduced hemoglobin and oxyhemoglobin (Lundsgaard).

If the quantity of hemoglobin contained in the blood is decreased, there will be less reduced hemoglobin, and vice versa. This is why it is more difficult to find cyanosis in anemic patients, on the contrary, cyanosis is much more readily found in polycythemic patients. In polycythemia, "which is not secondary to arterial disease," the percentage of oxygen saturation (in both the venous and systemic blood) is normal but the absolute value of reduced hemoglobin can be increased over the threshold of cyanosis simply as a consequence of the unusual increase in number of red blood cells (Selzer).

Finally one should remember that often both central and peripheral mechanisms act together and, in certain conditions, are modified by peripheral factors, such as the number and size of capillaries and the thickness and pigmentation of the skin.

### CLUBBING

Clubbing of fingers and toes is characterized by a rounded, thick appearance of the distal phalanges. *Periostitis*, mainly of the long bones, is frequently associated with it, and there may be joint symptoms (Gall et al.).

anism. In hyponatremia (not therapeutically induced), water is retained, although the concentration of sodium is lower than normal. In spite of this, more sodium than water seems to be retained. This demonstrates that a certain amount of sodium is preserved in body reservoirs (bones, cartilages, connective tissue) (Mokotoff et al.; Talso et al.), or possibly within the cells.

The fact that in some endocrine conditions, either spontaneous or artificially induced by corticosteroids, sodium retention and edema are observed, led to the theory that renal retention of sodium in cardiac failure is mediated through hormonal factors. Certain authors have found a greater elimination of glucocorticoids (Parrish) and especially of aldosterone (Avelrad et al.; Davis et al., Pechet et al.). The same finding has been obtained in experimental animals (Davis et al.). However, this increase in the urinary excretion of aldosterone has not been confirmed by others (Driscoll et al.; Muller et al.). The observation that the urinary elimination of aldosterone in dogs after ligation of the inferior vena cava gradually rises while, at the same time, ascites is present, led to the belief that the increased secretion of aldosterone is not necessary to initiate water and sodium retention, and that its greater elimination is the result, not the cause, of this retention.

The most interesting point is that in normal dogs (Davis et al.) or dogs with bilateral adrenalectomy (Gaudino et al.), the administration of large doses of DCA produces only a transitory retention of sodium. On the contrary, there is an almost complete retention of sodium, accompanied by formation of ascites, when DCA is administered to adrenalectomized dogs after the ligation of the inferior vena cava (Davis et al.). Besides, in normal persons, in whom the intake of sodium was reduced to 11 mEq daily, greater elimination of aldosterone was found. It is evident that the edema of experimental cardiac failure cannot be produced if there is no adrenal activity. It is possible that in the edematous state, there is no adrenal hypersecretion but simply a difficulty in the hormonal destruction, caused by the functional impairment of the liver (Laragh et al.).

The retention of sodium precipitates a greater secretion of pituitary antidiuretic hormone, and this increases the reabsorption of water in the distal tubules and water reten-

tion. Consequently, this is a factor that intervenes only in a second, late stage. Hyponatremia observed spontaneously in patients with severe congestive failure suggests that, in certain conditions, antidiuretic hormone production is independent of osmoreceptor control (Hansson et al.).

A final summarization of the numerous studies leads to the conclusion that in the genesis of edema of cardiac failure, the initial and fundamental factor is the increase of hydrostatic pressure, causing the plasma to filter water and sodium in the interstitial spaces. A homeostatic mechanism starts acting and leads to retention of sodium in order to compensate for the loss.

## DISPNEA

Every normal person has "consciousness of the necessity to increase the respiratory effort" (Meakins) during severe physical exertion, especially if he has had no adequate training. This dyspnea may have a mechanism similar to that observed in cardiac failure. However, the latter has certain characteristic aspects: (1) It appears with physical effort or emotional states that previously did not produce respiratory difficulty; (2) it lasts longer than usual after the cause is removed, and (3) it impairs the functional capacity of the patient, preventing him from accomplishing an effort that was within his ability prior to the onset of failure.

That an abundant diuresis produced by mercurials is followed by a rapid relief of dyspnea proves that pulmonary venous engorgement plays an important role in the genesis of dyspnea.

Whether because of left ventricular failure or mechanical block (as in mitral stenosis), blood accumulates in the lungs, and the circulation becomes slower but occurs under greater pressure in the pulmonary venous and capillary systems. Loss of compliance of the lungs occurs, probably with compression of the alveoli, and interstitial and alveolar edema may occur.

The marked diminution of vital capacity, tidal volume, and inspiratory and expiratory reserve is then easily explained. Compensatory tachypnea increases the respiratory minute volume, but the maximal respiratory capacity is decreased because hyperpnea is obtained through an increase in respiratory rate, not of respiration.

believes that even in the absence of arterial unsaturation, clubbing may occur if there are accelerated sedimentation rate of the red cells and a wide vascular bed that favors the formation of intravascular *rouleaux*; the latter interfere with tissue oxygenation by a decrease of the diffusion surface per unit of hemoglobin.

### PERIPHERAL EDEMA

Edema of heart failure has been classically explained as one of the results of venous hypertension. The increase in hydrostatic pressure of the venous-capillary bed favors filtration of water and electrolytes in the intercellular spaces. The small amount of protein content of the edema fluid (0.2 to 0.5 per cent) (Stead et al.) shows that usually there is no increase of capillary permeability.

Many data confirm the importance of *venous hypertension* as the basic cause of edema. In venous obstruction (caused by compression, surgical ligation, following phlebitis, etc.), *local edema* is produced. In clinical or experimental hypoproteinemia, with or without renal lesions, edema is present because a "relative increase" of hydrostatic pressure is caused by the decrease of colloid osmotic pressure of the plasma.

Ligation of the inferior vena cava causes ascites if it is located above the hepatic veins, but not if it is placed between the latter and the renal veins. In acute left ventricular failure, pulmonary edema occurs.

The importance of the increased hydrostatic pressure in the genesis of edema has been, however, discussed or denied by some authors (Goldman et al., Warren et al.) because the same degree of venous hypertension may or may not be associated with edema in different clinical cases. Moreover, after disappearance of failure, the administration of sodium increases edema without an increase of venous pressure (Goldman et al., Warren et al.). When digitalis is discontinued in patients in failure on salt-poor diet, venous pressure may rise without increase of weight (Newman et al.; Reichsman et al.).

In general, this and other observations show that in spite of increased venous pressure, edema will not occur or will appear with difficulty if the body does not have abundant material to develop it. Besides, it is evident that exercise, hypoproteinemia, tissue pressure, etc., are secondary factors that may contribute to

the appearance and distribution of the edema of cardiac failure.

The hypothesis that increased venous pressure in cardiac failure is not a direct consequence of failure but *is due to the increased blood volume*, caused by sodium and water retention, plus the effect of *reflex venoconstriction*, cannot be accepted without reservation.

The fact that severe experimental lesion of the right ventricle does not produce venous hypertension (Starr et al.) is not a decisive proof, because in this condition, venous return to the left ventricle is also severely decreased. With an extracorporeal pump maintaining left ventricular output in a dog, in which acute right ventricular failure had been produced, venous pressure becomes a linear function of left ventricular output. On the contrary, this does not happen when the right ventricle works normally. This confirms that right ventricular failure is the direct cause of the increase in venous pressure and circulating blood volume (Rose et al.).

Several investigators claim that edema in cardiac failure is due to diminution of renal excretion of sodium, followed by water retention. According to this theory, venous hypertension is a secondary phenomenon and would determine only the appearance and localization of the edema. The hypothesis that this decrease of renal excretion of sodium is caused by a diminution of glomerular filtration as a result of reduced renal blood flow is, for many reasons, untenable.

In fact, there are numerous proofs that in cardiac failure there is an increase in tubular reabsorption of sodium. If water and sodium are exuded from the plasma to the intercellular spaces, a homeostatic mechanism tends to retain water and sodium in the body in order to compensate for the loss. It should be kept in mind that in cardiac failure, the amount of interstitial fluid becomes greater than the total amount of plasma (Friedberg). At the same level of elevated hydrostatic pressure, edema increases when a patient's diet contains too much sodium and decreases when sodium is restricted or is eliminated by means of diuretics.

Water retention appears to be fundamentally secondary to sodium retention, since it is necessary to maintain the isotonic state.<sup>2</sup> However, water can be retained through other mecha-

<sup>2</sup> See also Part 18, Chap. 4 Editor.

duces real relief is the vertical (thus the name *orthopnea*). In the supine decubitus, pulmonary congestion increases as a result of increased cardiac output and venous return. It is also possible that in the supine position, the sensitivity of the respiratory center is increased as a consequence of these circulatory changes or other unknown mechanisms; in some patients, elevation of the head by means of one or two pillows is sufficient to give relief, though some orthopnea still persists (Harrison).

In severe and protracted dyspnea at rest, expiratory wheezes and rales can be heard, simulating those of bronchial asthma. Spirograms are also similar in both conditions. Both bronchospasm and bronchial edema play a role in causing this type of respiration and aggravate dyspnea, as demonstrated by the fast relief that follows the administration of aminophylline, ACTH, or prednisone.

Paroxysmal dyspnea and acute pulmonary edema have a similar pathogenesis and must be considered as the most severe degree of cardiac dyspnea. Evidently they are due to a sudden occurrence or intensification of pulmonary congestion. Whatever the factors of congestion, it is evident that this is the basic cause of the paroxysmal attacks, as demonstrated by the relief obtained through the orthopneic position and the beneficial effect of venesection. However, it is not easy to explain why the attacks appear predominantly at night and paroxysmally. Increased venous return caused by the supine position, and possibly by sleep (Halmagyi et al.), is probably one factor. To this should be added at times an increase of circulating plasma due to hemodilution, favored by the recumbent position (Perera et al.).

It is likely that during sleep, the respiratory center has a lower sensitivity and does not react proportionally to the increase of centripetal impulses determined by the pulmonary congestion. As soon as the patient awakes, as a result of this condition or for any other cause, the center recovers its sensitivity and reacts with intense hyperpnea.

When the increase of pulmonary congestion is severe and sudden, especially if the patient has not developed an increase of the pulmonary arteriolar resistance, the hydrostatic pressure of the pulmonary capillaries becomes higher

than the threshold of 25 to 35 mm Hg, and transudation of fluid occurs. This fluid accumulates in the alveoli, interalveolar spaces, and bronchial walls beyond the capacity of reabsorption of the pulmonary lymphatic vessels (Dunkler et al.).

**Dyspnea in Neurocirculatory Asthenia.** Patients without cardiac failure, with or without organic cardiac disease, may have tachypnea and dyspnea of effort, or even at rest, besides the other characteristic manifestations of functional cardiovascular disease (Friedman). These patients have a tendency to use the diaphragm only slightly during normal respiration and to breathe chiefly with the intercostal and accessory muscles. The time of apnea after a period of forced hyperventilation does not increase significantly with respect to the one registered before the test; this is characteristic of this condition (Friedman).

This type of dyspnea is associated more frequently than is generally realized to the dyspnea of cardiac failure, and, in some cases, may aggravate or precipitate attacks of paroxysmal dyspnea because tachypnea facilitates venous return to the right heart, thus increasing pulmonary congestion.

**Cheyne-Stokes Respiration.** The periodic respiration of Cheyne-Stokes is due to diminished stimulation of the respiratory center, in the presence of either normal sensitivity with *hypocapnia* (as in high altitudes or during forced hyperventilation) or, more commonly, decreased sensitivity with normal concentration of carbon dioxide in the blood. Both factors often occur simultaneously.

When the stimulation of the respiratory center is decreased, a period of apnea is produced, usually in an expiratory position (Wassermann). The interruption of pulmonary ventilation causes the accumulation of carbon dioxide in the arterial blood (*hypercapnia*) and *hypoxia*. When hypercapnia and hypoxia reach the maximum, the respiratory center is intensely stimulated, both directly and through stimuli acting on the chemoreceptors. Then a phase of hyperpnea supervenes, in which the retained carbon dioxide is eliminated, anoxia is corrected, and the patient returns to the apneic period.

The fundamental factor that causes and perpetuates periodic respiration is not the lack of

\* See Part 18, Chaps 10 to 14 for details pertaining to pulmonary edema, Editor.

\* See also Part 17, Chap. 2 Editor.

Hepatomegaly, abdominal distention, ascites, and pleural or pericardial effusion, when present, increase intrapleural pressure and aggravate the effects of pulmonary congestion.

In spite of these changes, there is no alteration of blood oxygenation, except in advanced cases or those with pulmonary complications.

The following facts demonstrate that the different types of dyspnea in cardiac failure result from pulmonary congestion, not from alterations of the respiratory center or changes of blood chemistry.

1. Neither diminution of cerebral blood flow (Moyer et al.; Novak et al.) nor increase in the arteriovenous difference of oxygen between carotid and internal jugular bloods (Cullen et al.) has been demonstrated. Moreover, there are conditions (such as shock) in which cardiac output is diminished but dyspnea does not occur.

2. Oxygen saturation of the arterial blood is normal in patients with dyspnea (Meakins, Novak et al.) or is only slightly subnormal (Platts), at rest as well as after moderate exercise (Cullen et al.). Only in severe cardiac failure, cardiac failure with pulmonary complications, or after extreme effort, does one find low levels of oxygen saturation that can stimulate the chemoreceptors (Ruskin). Patients with congenital malformation of the heart and severe oxygen arterial unsaturation may not have dyspnea. This demonstrates that the diminution of oxygen in the venous blood has no importance as a factor of excitation of the peripheral respiratory chemoreceptors (Aviado et al.). However, a moderate diminution of oxygen arterial saturation might contribute to stimulation of the respiratory center if this is already abnormally stimulated by other impulses.

3. Dyspnea cannot be attributed to an increase in carbon dioxide of the arterial blood, first, because carbon dioxide is easily eliminated by hyperventilation, and, second, because of its greater diffusion from the alveolar walls. Therefore, except when there are severe pulmonary complications, the amount of carbon dioxide in the arterial blood, alveolar air, and exhaled air may even be lower than normal (Harrison).

4. This behavior of carbon dioxide explains the eventual occurrence of alkalosis (Fraser et al.) in left ventricular failure with dyspnea. On the other hand, when there is pulmonary involvement with hypoventilation, *hypercapnia*

may occur, followed by acidosis. In severe and advanced cardiac failure following renal insufficiency or due to ammonium chloride, or after severe exercise, acidosis may appear. It is then due to accumulation of lactic and pyruvic acids and will increase the severity of the dyspnea. This type of dyspnea, however, tends to lose its superficial character and assumes that of deep hyperventilation, as seen in diabetic acidosis (Friedberg).

**Mechanism by Which Pulmonary Congestion Originates Dyspnea.** The decreased compliance of the lungs and the decreased distention of the alveoli increase the discharge of centripetal impulses that stimulate vagal terminations and originate tachypnea (Harrison). It is possible that the distention of pulmonary vessels (Aviado et al.) contributes to produce or exaggerate tachypnea by a reflex vagal mechanism (Churchill-Cope).

The various factors have more or less importance according to the different types of dyspnea. In *exertional dyspnea*, pulmonary reflexes are elicited by the pulmonary congestion, which is the result of a markedly increased cardiac output, and have great importance. Muscular contraction or passive muscular movements may produce hyperventilation; the latter disappears after nerve section (Harrison). The author does not believe that these reflexes are the basic cause of dyspnea in patients with cardiac disease, because the dyspnea increases progressively and is then transformed into dyspnea at rest. Besides, in any of these situations, the therapeutic decrease of pulmonary congestion lessens dyspnea. It is probable that during intensive effort, secretion of hormones (epinephrine), accumulation of acids (lactic acid) and other metabolites, as well as hypoxia and hyperthermia may all be contributory factors.

In *dyspnea at rest*, pulmonary congestion is greater and is followed by the various mechanical and reflex changes that have already been discussed. This type of dyspnea increases in the supine position, thus is a useful sign in differentiating it from other types of dyspnea.

The patient usually avoids left lateral decubitus because it produces more dyspnea (*trepopnea*) (Wood et al.). This is possibly because of gravitational shift of the enlarged heart, diminution of venous pulmonary drainage, and increase of pulmonary inflow with decrease of vital capacity (Ruskin). The position that pro-

oxygen but the diminished reactivity of the respiratory center to carbon dioxide. For this reason, inhalation of oxygen prolongs the periods of apnea (Harrison, Uhlenbruck) while inhalation of carbon dioxide regularizes respiration. The oxygen saturation has been found normal in patients with cardiac failure and Cheyne-Stokes respiration (Anthony et al., Currens et al.).

The sensitivity of the respiratory center may be decreased by numerous local and general factors, cardiac failure, atherosclerosis of cerebral vessels, tumors and other lesions of the nervous centers, hypertension of the spinal fluid, sleep and certain drugs (morphine, etc.). Cheyne-Stokes respiration may be a normal phenomenon in children (especially in those born prematurely) and in the aged during sleep (Scherf and Boyd).

In many patients, this respiratory alteration is accentuated by the beginning of sleep, and

the latter is interrupted by the phase of hyperpnea. This is one reason why certain patients with cardiac failure have great difficulty in falling asleep. However, at times Cheyne-Stokes respiration disappears when the sleep is deep, probably because in this condition, the tension of carbon dioxide in the blood is increased (East et al.). Cheyne-Stokes respiration has been observed during Stokes-Adams attacks. Hyperpnea coincides with the arrest or decrease of the ventricular rate (*Fulton's paradox*). However, in many circumstances, the opposite occurs and Cheyne-Stokes respiration produces AV block (Bullrich et al.).

The mechanism by which aminophylline relieves Cheyne-Stokes respiration is not well known, although it has been attributed to a direct stimulating action on the respiratory center or to a greater local accumulation of carbon dioxide caused by reduction of cerebral blood flow (Moyer et al.).

## GALLOP RHYTHM; ALTERNANS

### TRIPLE AND QUADRUPLE RHYTHMS OF THE HEART

The names *triple rhythm* and *quadruple rhythm* have been suggested to indicate those cadences which are due to addition of one or two diastolic sounds to the more commonly heard two heart sounds. Older and well-known names were *gallop rhythm* and *train-wheel rhythm*. The new terms are more comprehensive and include several possibilities not previously considered.

As already mentioned (Part 2, Chap. 10, and Part 3, Chap. 9, Technical Aspects of Phonocardiography), the normal heart may have four sounds. The two loudest are the 1st and 2d sounds, at the beginning and end of ventricular systole (*systolic sounds*), the other two, of lesser intensity, occur during ventricular diastole, respectively coinciding with the two phases of rapid filling of the ventricles (*diastolic sounds*). They are the 3d sound (which falls at the peak of the phase of rapid, passive filling) and the 4th, or *atrial*, sound (which occurs in coincidence with atrial contraction). They are usually inaudible in adults, except in persons with a flat, thin chest, who may have an audible 3d sound.

The atrial (or 4th) sound is audible on auscultation only in pathologic conditions. How-

ever, phonocardiographic tracings reveal either one or two small, low-frequency vibrations in presystole in many normal subjects, especially if they are young. These deflections have been regarded as consisting of two different components (1) a low-amplitude group of vibrations associated with *atrial contraction*, (2) a larger group, occurring 0.05 to 0.09 sec later (Weitzman), which is attributed to ventricular distention (Cossio and Braun-Menéndez; Kincaid Smith and Barlow, 1959a; Kuo et al.; Leonard et al.). This second group has also been related to tensing or closure of the AV valves before the onset of ventricular contraction (T. Lewis), and actual, though not completely convincing, evidence for such movements has been reported by several authors (Little; Little et al., Ankeney et al., Moscovitz and Wilder; Yoshida et al., 1960).

Since contraction of the right atrium precedes that of the left, it is logical to assume asynchronism between right and left atrial sounds. This may further confuse the correlation with mechanical events.

In an experimental study correlating intracardiac pressures with intracardiac sounds, Mmesan et al. concluded that the first group of vibrations was due to atrial contraction, and the second, to ventricular filling. However, a short reversal of pre-

production of the late component or the atrial sound

In regard to the 3d sound, in the past, a triple rhythm (gallop) was considered as a purely auditory phenomenon. However, phonocardiography has revealed that in certain persons with a triple rhythm, a diastolic sound is rather large but is inaudible because it is weak, low-pitched, or too near the 1st sound.

The author, together with Roitman, tried to separate the cases with a more "physiologic" triple rhythm from those with a more "pathologic" triple rhythm. It was decided to classify as "more pathologic" any case having a diastolic sound with the following graphic characteristics: (1) frequency of vibrations of 30 or more per second, irrespective of its amplitude; (2) amplitude greater than two-thirds of the loudest of the two main sounds at the apex, or (3) both. This empirical classification has no absolute value because the "pathologic" is merely the accentuation of a "physiologic" phe-

Fig. 5-7. A Hypertensive and coronary heart disease. Stethoscopic and linear tracings at apex. Quadruple rhythm due to large 3d and 4th sounds. B Hypertensive and coronary heart disease. Stethoscopic and linear tracings at apex. Triple rhythm due to large 3d sound in early diastole.

nomenon, and the pitch of the pathologic sound may be similar to that of the normal sound. More recently, Friedland and Jacono studied the triple rhythms by means of filters (Part 3, Chap. 9). The conclusion was that, in some pathologic cases, the frequency of the vibrations of the extra sounds is the same as that of the normal extra sounds (3d and 4th sounds).

**Phonocardiogram, Low-frequency Tracings.** Three types of triple rhythm have been recognized (Wollerth and Margolies; Braun-Menéndez) (Fig. 5-8).

1. **Atrial type** The additional sound occurs at the time of atrial contraction and represents the accentuation of the 4th sound (Fig. 5-8A). It usually falls in late diastole, but if the P-R interval is long and diastole is short, it may fall in mid-diastole or even early diastole.

2. **Ventricular type** The additional sound falls in early diastole, at the time of rapid filling, and represents the accentuation of the 3d sound. It occurs from 0.14 to 0.18 sec after the 2d sound in adults (Fig. 5-7B).

3. **Summation (or "nondescript") type.** There is an additional sound or a short, rumbling murmur in mid-diastole. This is due to the more or less simultaneous occurrence of the two sounds.

Fig. 5-6. Scheme of triple and quadruple rhythms. A. Normal. B. Triple rhythm (large 4th sound). C. Triple rhythm (large 3d sound). D. Triple rhythm (summation type). E. Quadruple rhythm (large 3d and 4th sounds). (From Luisada, *Heart Beat*, Hoeber, New York, 1953)

oxygen but the diminished reactivity of the respiratory center to carbon dioxide. For this reason, inhalation of oxygen prolongs the periods of apnea (Harrison; Uhlenbruck) while inhalation of carbon dioxide regularizes respiration. The oxygen saturation has been found normal in patients with cardiac failure and Cheyne-Stokes respiration (Anthony et al.; Currens et al.).

The sensitivity of the respiratory center may be decreased by numerous local and general factors; cardiac failure, atherosclerosis of cerebral vessels, tumors and other lesions of the nervous centers, hypertension of the spinal fluid, sleep, and certain drugs (morphine, etc.). Cheyne-Stokes respiration may be a normal phenomenon in children (especially in those born prematurely) and in the aged during sleep (Scherf and Boyd).

In many patients, this respiratory alteration is accentuated by the beginning of sleep, and

the latter is interrupted by the phase of hyperpnea. This is one reason why certain patients with cardiac failure have great difficulty in falling asleep. However, at times Cheyne-Stokes respiration disappears when the sleep is deep, probably because in this condition, the tension of carbon dioxide in the blood is increased (East et al.). Cheyne-Stokes respiration has been observed during Stokes-Adams attacks. Hyperpnea coincides with the arrest or decrease of the ventricular rate (*Fulton's paradox*). However, in many circumstances, the opposite occurs and Cheyne-Stokes respiration produces AV block (Bullrich et al.).

The mechanism by which aminophylline relieves Cheyne-Stokes respiration is not well known, although it has been attributed to a direct stimulating action on the respiratory center or to a greater local accumulation of carbon dioxide caused by reduction of cerebral blood flow (Moyer et al.).

### GALLOP RHYTHM; ALTERNANS

#### TRIPLE AND QUADRUPLE RHYTHMS OF THE HEART

The names *triple rhythm* and *quadruple rhythm* have been suggested to indicate those cadences which are due to addition of one or two diastolic sounds to the more commonly heard two heart sounds. Older and well-known names were *gallop rhythm* and *train-wheel rhythm*. The new terms are more comprehensive and include several possibilities not previously considered.

As already mentioned (Part 2, Chap. 10, and Part 3, Chap. 9, Technical Aspects of Phonocardiography), the normal heart may have four sounds. The two loudest are the 1st and 2d sounds, at the beginning and end of ventricular systole (*systolic sounds*), the other two, of lesser intensity, occur during ventricular diastole, respectively coinciding with the two phases of rapid filling of the ventricles (*diastolic sounds*). They are the 3d sound (which falls at the peak of the phase of rapid, passive filling) and the 4th, or atrial, sound (which occurs in coincidence with atrial contraction). They are usually inaudible in adults, except in persons with a flat, thin chest, who may have an audible 3d sound.

The atrial (or 4th) sound is audible on auscultation only in pathologic conditions. How-

ever, phonocardiographic tracings reveal either one or two small, low-frequency vibrations in presystole in many normal subjects, especially if they are young. These deflections have been regarded as consisting of two different components. (1) a low-amplitude group of vibrations associated with atrial contraction, (2) a larger group, occurring 0.05 to 0.09 sec later (Weitzman), which is attributed to ventricular distention (Cossio and Braun-Menéndez; Kincaid Smith and Barlow, 1959a; Kuo et al.; Leonard et al.). This second group has also been related to tensing or closure of the AV valves before the onset of ventricular contraction (T. Lewis), and actual, though not completely convincing, evidence for such movements has been reported by several authors (Little, Little et al., Ankeney et al., Moscovitz and Wilder, Yoshida et al., 1960).

Since contraction of the right atrium precedes that of the left, it is logical to assume asynchronism between right and left atrial sounds. This may further confuse the correlation with mechanical events

In an experimental study correlating intracardiac pressures with intracardiac sounds, Muesen et al. concluded that the first group of vibrations was due to atrial contraction, and the second, to ventricular filling. However, a short reversal of pre-

Fig 5-11. Normal subject Phonocardiogram (filter at 50 cps) (above), acceleration tracing of the precordium (center), and electrocardiogram. The acceleration tracing reveals better than the phonocardiogram the large presystolic wave that coincides with the 4th sound.

apex and then at the epigastrium (or 3rd left interspace), or simultaneously over both areas, reveal whether the triple rhythm originates in the left or in the right ventricle. A triple rhythm recorded *only* at the apex usually reveals left ventricular strain; a triple rhythm recorded *only* in the epigastrium usually reveals right ventricular strain. In exceptional cases, triple rhythms are recorded over both areas (Fig. 5-12), indicating biventricular strain.

The following conditions increase the loudness of the diastolic sounds:

1. *Rapid heart action.* The short diastole causes a tumultuous filling of the ventricles.
2. *Prolonged interval between atrial and ventricular contractions.* The increased interval permits a better audition but does not change the graphic characteristics of the atrial sound.
3. *Hypertrophy of the left atrium,* as observed in mitral insufficiency without marked

mitral stenosis, is the cause of a powerful atrial contraction, which displaces a large amount of blood. The same is true for the *right atrium* in cor pulmonale or severe mitral stenosis with relative tricuspid insufficiency or in cases of organic tricuspid insufficiency or atrial septal defect. In these cases, there is an increase of the 3d sound.

4. *Dilated and weak myocardium.* The ventricular wall has greater vibration when hit by the fluid wave. This is common in congestive failure and in coronary heart disease.

5. *Ventricular strain* favors triple rhythms through increase of left ventricular diastolic pressure and atrial filling pressure; this is typical of hypertensive heart disease with left ventricular strain.

The reason similar conditions may cause large 3d or 4th sounds tentatively may be explained as follows:

Fig 5-8. A Hypertensive heart disease Phonocardiograms at apex and ECG. From above Filtered phonocardiogram (30 to 60 cps) "Stethoscopic" phonocardiogram ECG Triple rhythm due to large 4th sound in presystole B Coronary heart disease Heart failure. Quadruple rhythm due to large 3d and 4th sounds. Each of these diastolic sounds is followed by a short rumble (Upon auscultation impression of a diastolic rumbling murmur)

sion, of the 3d with the 4th sounds (Fig 5-9)

When diastole is long (bradycardia), and both the 3d and 4th sounds are large, one may observe.

4. *Quadruple rhythm.* There are two additional sounds in diastole, representing the accentuation of the 3d and 4th sounds (Fig 5-7A), which are separated from each other.

Each diastolic sound is made of a high di-phasic or triphasic vibration when recorded with a "stethoscopic" system or a filtered system in the low range (30 to 69 cps). In higher bands (80 to 120 or 120 to 140 cps), occasionally two to three small rapid vibrations may be recorded. The extra sound is simultaneous with a high wave in the ultra-low-frequency tracing (linear cardiogram at apex and epigastrium). In the summation type, two distinct waves may be present in the ultra-low-frequency tracing, even if a prolonged sound or short rumble is revealed by the sound tracing.

Occasionally, pathologic 3d or 4th sounds,

or a summation sound, can be recorded even in the 240 to 480 cps range (Luisada and Di Bartolo) (Fig. 5-10).

The acceleration tracing at the precordium (range, 5 to 25 cps) reveals the diastolic vibrations better than any other type of tracing. Sometimes these vibrations are recorded by such a method even when the conventional phonocardiogram fails to reveal them (Rosa and Kunos) (Fig. 5-11).

Phonocardiograms recorded first over the

Fig 5-9. Phonocardiogram (stethoscopic) and low-frequency tracing (cardiogram) at apex in chronic glomerulonephritis with severe hypertension Summation type of triple rhythm The additional sound S corresponds to a diastolic forward thrust in the low-frequency tracing.

apex and then at the epigastrium (or 3rd left interspace), or simultaneously over both areas, reveal whether the triple rhythm originates in the left or in the right ventricle. A triple rhythm recorded only at the apex usually reveals left ventricular strain; a triple rhythm recorded only at the epigastrium usually reveals right ventricular strain. In exceptional cases, triple rhythms are recorded over both areas (Fig 5-12), indicating biventricular strain.

The following conditions increase the loudness of the diastolic sounds.

1. *Rapid heart action* The short diastole causes a tumultuous filling of the ventricles.
2. *Prolonged interval between atrial and ventricular contractions.* The increased interval permits a better audition but does not change the graphic characteristics of the atrial sound.
3. *Hypertrophy of the left atrium*, as observed in mitral insufficiency without marked

mitral stenosis, is the cause of a powerful atrial contraction, which displaces a large amount of blood. The same is true for the right atrium in cor pulmonale or severe mitral stenosis with relative tricuspid insufficiency or in cases of organic tricuspid insufficiency or atrial septal defect. In these cases, there is an increase of the 3d sound.

4. *Dilated and weak myocardium* The ventricular wall has greater vibration when hit by the fluid wave. This is common in congestive failure and in coronary heart disease.

5. *Ventricular strain* favors triple rhythms through increase of left ventricular diastolic pressure and atrial filling pressure, this is typical of hypertensive heart disease with left ventricular strain.

The reason similar conditions may cause large 3d or 4th sounds tentatively may be explained as follows:

**Fig. 5-12.** Biventricular triple rhythm (right and left gallop). Simultaneous phonocardiograms at apex and midprecordium in severe mitral insufficiency. The large 3d sound at apex (left ventricle) precedes that at the midprecordium (right ventricle).

*a* A large 4th sound occurs when the diastolic pressure rises in one ventricle and the respective atrium increases the power of its contraction (left or right ventricular failure-atrial systolic overload).

*b* A large 3d sound occurs when the filling of an atrium is increased (atrial septal defect, tricuspid insufficiency, mitral insufficiency-atrial diastolic overload).

A diastolic type of triple rhythm<sup>a</sup> is recognized by recording simultaneously a phonocardiogram and an ultra-low-frequency (linear cardiogram) or a low-frequency (accelerogram) tracing at the apex or epigastrium. The atrial type is also well recognized by comparison with an electrocardiogram: the additional sound precedes the QRS complex.

In differential diagnosis between splitting of

the 2d sound, opening snap of the mitral valve, and a diastolic sound, apart from the time coincidence with the waves of the low-frequency tracing (cardiogram) and the electrocardiogram, one may also make use of the following average figures for adults (the intervals are shorter in children)

1. The distance between the two phases of a split 2d sound varies between 0.025 and 0.05 sec (this interval was formerly thought to be 0.03 to 0.11 sec, but the last figure should not be accepted)

2. The distance between the aortic component of the 2d sound and the opening snap of the mitral valve varies in adults between 0.06 and 0.11 sec (formerly thought to be 0.07 to 0.13).

3. The distance between the aortic component of the 2d sound and the beginning of the 3d sound varies between 0.12 and 0.18 sec.

A dull 3d sound is normal in children or

<sup>a</sup> Addition of a sound in systole causes a *systolic* type of triple rhythm

Fig. 5-13. Pulsus alternans. A. ECG and brachial pulse tracing. The pulse presents severe alternation. The ECG has phasic respiratory variations but no alternans. B. Phonocardiogram over aortic area and brachial pulse tracing. There is alternation of the pulse and of the 2d aortic sound.

young persons with a thin, flat chest. It is abnormal in older persons or if it is very large. A 4th sound may be recorded (seldom heard) in normal subjects above the age of 40. It becomes an abnormal phenomenon if it is found in younger persons or if the vibration is large or high-pitched.

As already stated, triple and quadruple rhythms are commonly associated with tachycardia, ventricular dilatation, or ventricular strain. Therefore, these rhythms are frequently encountered in pregnancy, thyrotoxicosis, fever, anemia, constrictive pericarditis, rheumatic or congenital heart diseases, and hypertensive or coronary heart diseases. They are also typical of heart failure. They are frequently found after a myocardial infarct. The rhythm is caused by functional phenomena, which may disappear (delivery, sedation, digitalization, mitral surgery, sympathectomy, or venesection), causing a return to normal of the auditory phenomena.

While a triple rhythm is more frequent in patients with cardiac disease than in normal subjects, it may be found occasionally even in the latter because its production is favored by functional elements that may be present without heart disease.

The term "triple rhythm" should be preferred to others in order to dispel the unjustified fears once attached to the term "gallop rhythm." However, it should be kept in mind that a triple rhythm is evidence of a definite functional disturbance of the heart.

One important observation is that, in heart failure, mechanical systole may have a different duration from that of electrical systole (Hegglin). This is typically revealed by comparing a phonocardiogram with an electrocardiogram. The description of this phenomenon can be found in Part 18, Chap. 9.

### ALTERNANS

Pulsus alternans occurs when every other pulse wave is weak although there is no irregularity of the heart (Fig 5-13).<sup>4</sup> It may appear during attacks of paroxysmal tachycardia. It is typical of hypertension, coronary heart disease (especially after myocardial infarction), and congestive failure.

Pulsus alternans is recognized by palpation of the radial pulse only when it is exceptionally

<sup>4</sup> Recent studies have shown that it is possible to recognize alternans even when the heart rhythm is irregular.

Fig. 5-14. A. Phonocardiogram and brachial tracing at 90 mm. Alternation of heart sounds (discordant alternation of the 1st sound, concordant alternation of the 2d sound). There is a questionable pulse wave in cycle 2, and a more visible one in cycle 6. B, C. Brachial tracings above arterial sounds. Below arterial pulses. Both are simultaneously recorded by two crystal microphones from a recording cuff inflated at 25 mm. The compressing cuff had a pressure of 90, pulse wave but no arterial sound (stethoscopic halving). In tracing C, a deep respiration disturbs the sequence, causing larger pulses. cycles 6 and 8 have no pulse and no arterial sound (sphygmographic and stethoscopic halving). (From Liu and Lusada, *Am Heart J*, 1955.)

severe. Manual compression of the brachial artery may cause halving of the pulse, thus revealing less-marked alternation.

Blood pressure tracings easily reveal the alternans. If the patient has a heart rate of 60, decompression first shows the arterial sounds due to the large waves (rate of 30), then those due to all waves (rate of 60). A new halving of the rate may be observed near the level of diastolic pressure.

There are four types of alternating pulse (1) alternation of the peak (systolic alternation); (2) alternation of the foot (diastolic alternation), (3) alternation of both (systolic and diastolic alternation); (4) alternation of the diastolic wave. In exceptional cases, the tibial tracing fails to reveal an alternation that is present in the brachial tracing.

Several phenomena may alternate in pulsus alternans:

- 1 The intensity of the cardiac sounds, chiefly the 2d (Fig. 5-14)
- 2 The intensity of a murmur
- 3 The amplitude of the ventricular contractions as recorded by the electrokymograph (Fig. 5-15)
- 4 The amplitude of the pressure pulse of either the right or the left ventricle, as well as the pulses of either the aorta or the pulmonary artery

In rare cases, alternation may be so severe that the small pulse disappears. Then, there is *halving of the pulse* (Figs 5-13 and 5-14), a phenomenon that has been called *pulsus bisectus* (Liu and Lusada, 1955).

At times, the electrocardiogram reveals an alternation of P, R, T, or S-T, which may be *concordant* or *discordant* in relation to the pulse.

Exertion usually increases the alternation.

A premature beat may start the alternation, which usually continues for some time thereafter.

Differential diagnosis from a bigeminal pulse is made by observing an electrocardiogram and a pulse tracing. The ventricular complexes are identical in pulsus alternans, the unusual complex of a premature contraction periodically follows a normal complex in bigeminal pulse. The small wave is often nearer the preceding large wave in bigeminal pulse.

In certain cases with rapid respiration, the cardiac rate may be only twice the respiratory rate, simulating alternation of the pulse. Asking the patient to "hold his breath" for a few seconds reestablishes equal pulses.

**Mechanism.** Alternation of various cardiac functions has been described. *Alternating conductivity* leads to periodic changes of the P-R interval or to periodic AV block every second beat, and may cause an alternating bundle branch block. *Alternating automatism* has been advocated as the cause of bradycardia, similar to that of periodic SA block type 2:1. Simi-

larly, *alternation of the strength of ventricular systole* is the cause of pulsus alternans.

The most likely explanation is the following. A certain area of the ventricular myocardium (or a certain number of fibers here and there) possesses a *longer refractory period* than the rest of the heart, either because it has been damaged or because its blood supply is poor. When a stimulus reaches the ventricle after a long pause (respiratory arrhythmia, compensatory pause after a premature beat, or during slow rate caused by vagal reflex), all fibers contract, causing a large blood wave to enter the aorta. However, this contraction is followed by a diastole that is not sufficiently long to restore the damaged fibers. The following stimulus causes the contraction of all fibers, except those damaged (which are still in a relatively refractory period), whereupon a small blood wave enters the aorta. Then a large and a small wave alternate again until a change occurs in the heart rate or in the conditions of the myocardium. In other words, a difference in the length of the refractory period of some fibers

Fig 5-15. Electrokymograms and simultaneous sound tracings. A Left ventricular border in pulsus alternans. Alternation of diastole and systole with smaller waves in cycles 2 and 4. B Pulmonary knob. Alternation of pulmonic pulses. C. Aortic knob. Complete halving of the pulse. The small waves of cycles 2 and 4 should appear at the time of the 2d sounds (arrows). (From Liu and Lissado, *Am Heart J.*, 1955)

makes it possible that they contract only every other stimulus while all other fibers contract with every stimulus. Pulsus alternans indicates that a large number of cardiac fibers are in an abnormal functional condition. However, if the damaged fibers are in an area that has little or no influence on the size of the pulse, only other manifestations of cardiac activity reveal the disturbance, or it may not be apparent.

It is possible that pulsus alternans is caused occasionally by alternating changes in the tonus of the aorta and even in the tonus of one or more peripheral arteries. Proof of this, however, is not altogether convincing.

**Diagnosis.** Diagnosis of pulsus alternans is simple if it is remembered that it is a *regular pulse* with alternately smaller and larger waves. The phenomenon can be recognized by several maneuvers (manual compression of the brachial artery, inflated blood pressure cuff, exertion).

Differential diagnosis from a *bigeminal pulse* is easy with the aid of simultaneously recorded electrocardiogram and pulse tracing. The ventricular complexes are identical in pulsus alternans, while the complex of a premature con-

traction periodically follows a normal complex in bigeminal pulse. The small wave is *nearer the following large wave* (or is at an equal distance) in pulsus alternans; it is *nearer the preceding large wave* in bigeminal pulse.

In certain cases, if respiration is rapid, the cardiac rate may be one-half the respiratory rate. This may cause a nonpathologic alternation of the pulse. Asking the patient to "hold his breath" for a few seconds reestablishes equal pulses.

**Prognosis.** The pulsus alternans of paroxysmal tachycardia, and that occurring for only five to six contractions after a premature beat, are of limited importance. Nevertheless, they add severity to the syndrome. The pulsus alternans of all other conditions has a serious prognosis. Its importance should be evaluated together with all other clinical data, but there is no doubt that pulsus alternans is a serious sign.

Disappearance of pulsus alternans in a hypertensive patient, after surgery on the sympathetic system, treatment by hypotensive drugs, or thyroidectomy has been observed by the author and is evidence of marked improvement.

# Etiology and pathogenesis of congenital heart disease

MAURICE LEV AND ELISABETH KAVEGGIA

## ETIOLOGY

The etiology of congenital heart disease is today unknown. Various etiologic factors have been advanced as responsible in individual cases. They are (1) maternal factors, (2) genetic factors, (3) hypoxia and placenta previa, and (4) mongolism.

**Maternal Factors.** There is some evidence that there is an increased occurrence of congenital heart disease in the offspring of mothers over 40 years of age (Polan et al., Malpas). Likewise, there is a possible increase with the greater number of pregnancies (Lamy et al.). However, there is no evidence that chronic illness in the mother predisposes to congenital heart disease (Hartmann et al., Richards et al.). Rubella in the mother in the first trimester (Swan et al.; Weisselhoeft, Gregg, Ericson, Rutstein, and Albaugh), or even up to 3 months before gestation, is a definite factor in some cases (Swan, 1949), but of doubtful importance in the majority of instances (Lundstroem, Greenberg et al., Gibson). The abnormality frequently produced with rubella is patent ductus. Associated eye findings are frequent. Herpes simplex in the first trimester has been associated with occasional cases of tetralogy of Fallot (Richards et al.). Although general nutritional status of the mother may be a factor in the production of other abnormalities (Buerke et al., Stuart, Sandrucci), there is no evidence that this factor is related to congenital heart disease. Likewise, there is definite evi-

dence that irradiation of the mother may be related to the production of abnormalities in the fetus (Murphy, 1928 and 1929), but only an occasional case of congenital heart disease can be ascribed to this. Gynecologic disorders may be associated with mongolism and congenital heart disease (Ingalls, 1947; Lamy et al.).

**Genetic Factors.** Some cases of congenital heart disease appear to have a genetic etiology (Medvei and Roesler, Mildenberger, Jev, Blake, Stein and Barker, McKown et al.). Cases have been reported where father and son both had coarctation, two sisters both with Lutembacher's complex, three sisters with patent ductus, coarctation in the mother and patent ductus in two children, the same type of ventricular septal defect in the mother and in her 6-months-old fetus, hypoplasia of the aortic tract complex in two siblings, patent ductus in all six siblings. Likewise, consanguinity appears to be a factor in some cases.

**Other Etiologic Factors.** It has been clinically observed in one locality that patients suffering from patent ductus are more commonly born at higher altitudes than at sea level (Harrig). This suggests a possible hypoxic factor. Although placenta previa (Greenhill) and placental infarction (Talbot) are associated in some cases with other abnormalities, there is no evidence that they are related to congenital heart disease. Mongolism is definitely associated with congenital heart disease, especially com-

mon AV orifice, atrial septal defects, and transposition of the great vessels.

**Experimental Production of Congenital Heart Disease.** Congenital heart disease has been produced experimentally by (1) hypoxia in the fetus, (2) vitamin-A deficiency in the mother, (3) deficiency in pteroylglutamic acid in the mother, (4) administration of trypan blue and other azo dyes to the mother, and (5) irradiation of the fetus.

**HYPOXIA.** Many types of anomalies have been produced by hypoxic means, but congenital heart disease was found in only one series (Ingalls et al.). In this series, of 210 pregnant mice suffering hypoxia in 55 days of pregnancy, four fetuses showed ventricular septal defect, in three of which it was combined with other abnormalities.

**VITAMIN A DEFICIENCY.** Cardiac anomalies were produced in 28 of 64 newborn rats by vitamin A deficiency in the mother (Wilson and Warkany). The anomalies found were defect of ventricular and aortopulmonary septum and aortic arch malformations. These anomalies could be prevented by administration of vitamin A prior to the twelfth day of pregnancy (Wilson et al., 1953).

**DEFICIENCY OF PTEROYLGLUTAMIC ACID.** Deficiency of pteroylglutamic acid in the mother produced the following cardiac anomalies: ventricular septal defects, truncus arteriosus communis persistens, double or right aortic arch, absence of the ductus arteriosus, and aberrant origin of the subclavian arteries (Baird).

**TRYPAN BLUE.** The injection of trypan blue into pregnant rats has repeatedly produced congenital anomalies of the heart. The anomalies produced were ventricular septal defect, atrial septal defect, patent ductus, pulmonary stenosis or atresia (Rich-

duced a pathologic complex consisting of displacement of both atria, elongation of the heart, counterclockwise rotation of the heart, ventricular septal defect, dextroposition of the aorta, and pulmonary stenosis. The dye acts probably by altering the maternal metabolism since the dye is not found in the placenta or fetus, but in the reticuloendothelial system of the mother (Fox and Goss).

**IRRADIATION.** Irradiation of rat embryos directly through the abdominal incision of the mother caused the following developmental defects: situs inversus, failure of development of the foramen secundum, transposition of the great vessels, right or double aortic arch, truncus communis, atrial and ventricular septal defects, and common AV orifice (Wilson et al., 1953).

**HORMONES.** Although abnormalities have been produced by the administration of ACTH, cortisone (Fraser and Feinstat), and anterior pituitary extract (Fraser and Feinstat), no congenital heart disease has been found to date.

## **PATHOGENESIS**

Although the etiology is obscure, it can be assumed that some factor acts during the first two months of pregnancy to produce an abnormality in the development of the heart. This abnormality may be considered to be purely *embryologic*, or, in addition, a *phylogenetic factor* may be assumed to be operating in the production of some abnormalities. It is therefore essential to introduce the subject with a brief summary of the development of the heart phylogenetically and embryologically.

**Phylogenetic Development of the Vertebrate Heart.** The evolution of the mammalian heart is part of the evolution of the circulation of vertebrates, which is related to the progress of life as it emerged from sea water to fresh water and from fresh water to land. The outstanding characteristics of terrestrial habitat are (1) the presence of a relatively tremendous amount of oxygen in the atmosphere, (2) the low viscosity of the air, permitting rapid motion, (3) the marked fluctuations in temperature, and (4) the relative absence of water. The development of the circulation of vertebrates, although correlated with adaptations to all these environmental factors, was mostly related to the increasing ability to utilize oxygen.

With a change from a water to a land environment, lungs were developed with a gradually increasing amount of respiratory epithelium. This made possible increased absorption of oxygen and increased liberation of carbon dioxide, greater than that possible in gill-bearing vertebrates. This in turn resulted in fundamental changes in the transport of these substances and in the giving of the one and the removal of the other from the body cells. There thus ensued marked changes in the physiology and morphology of the circulation. The physiologic changes were (1) an increased efficiency of the pump, (2) an increase in the oxygen-carrying capacity of the blood, and (3) an increase in oxygen tension. The increased efficiency of the pump was obtained by (1) an increase in pressure, (2) an increase in speed of transmission of the excitation process, (3) an increase in heart ratio, and (4) an increase in rate. All these may be said to have been catalyzed mostly by the oxygen in the atmosphere and the circumstances available for its utilization, reinforced by homeothermism in birds and mammals (Clark).

The associated morphologic changes concerned

themselves mostly with the heart. The evolution in cardiac structure in vertebrates involves a change from the single circulation found in the fish with a four-chambered heart, whose chambers are arranged in series, to a double circulation of interchanging blood, found in the bird and mammal with a four-chambered heart, two of whose chambers are arranged in parallel to the other two (Spitzer). This remarkable change is brought about in two phases of development (Pernkopf and Wutinger)

In the first phase, the straight-tubed heart bends and twists upon itself in the form of an atrio-ventriculobulbar loop and bayonet-shaped bulbus. Concomitant with this is the beginning formation of septa and cushions in the atria and bulbus. This is as far as the development proceeds in the amphibia. In the second phase, the bulbus is absorbed into the ventricles. Concomitant with this is the completion of septation, the reorientation of the atria and ventricles, the absorption of the sinus venosus, and the development of valves. In reptiles, this process proceeds only partially, with incomplete septation in the ventricles. In birds and mammals, the complete separation of the circulations occurs.

The transition from the reptilian to the mammalian stage of circulatory development is important for the understanding of congenitally abnormal hearts. In the reptilian truncus, two septa develop, a septum aorticopulmonale and a septum aorticum, which eventually divide the vessel into three parts—two aortas and a pulmonary artery. In the mammal, only a septum aorticopulmonale develops, dividing the truncus into two vessels—a single aorta and a pulmonary artery. Likewise, in the reptilian bulbus, three ridges develop (1A, 4B, and 3C), which eventually form two septa, dividing the bulbus into three conus, one for each aorta and one for the pulmonary artery. In the mammalian bulbus, only two ridges develop (1A and 3B), which . . .

the bul . . .

the bul . . .

from the right ventricle, with an aorta from the left ventricle.

There is some evidence in favor of the hypothesis that hydrodynamic factors are in part responsible for the changes in the circulation in the ascending series of the vertebrates. These are the progressive increase in blood volume and pressure, catalyzed and augmented by the development of lungs. The increase in volume and pressure might be respon-

sible for the initial division of the cardiac tube into sinus venosus, atrium, ventricle, and bulbus; the subsequent absorption of the bulbus and sinus venosus, and the formation of septa throughout the heart tube (Diagram 6-1) (Spitzer, Lev and Saphir, 1945).

*The Embryologic Development of the Heart.*<sup>1</sup> The human heart arises from paired primordial thickenings in the splanchnic mesoderm, situated lateral to the primitive pharynx. From a proliferation of these cardiogenic plates, cells become separated and form elongated endothelial tubes on each side of the primitive gut. Two constrictions subsequently divide these tubes into three parts, a cephalic or bulbar, a middle or ventricular, and a caudal atrial region. With the formation and separation of the floor of the foregut from the yolk sac, the endothelial tubes swing medialward and progressively fuse ventral to the foregut anteriorly and posteriorly. Above and below this fused endothelial tube, the cardiogenic plates likewise come together, forming the epimyocardial mantle. The fusion of the cardiogenic plates dorsally forms the dorsal mesocardium. No ventral mesocardium is formed in the human embryo. The dorsal mesocardium subsequently disappears, and the heart is now freely suspended in the adjacent primitive coelom, which thus forms the pericardial cavity. At this stage, the heart consists of a tubular structure made up of the following: (1) the bulbus, (2) the primitive ventricle, (3) the primitive

<sup>1</sup> See also Part I, Chap. 1, p. 12.

mon AV orifice, atrial septal defects, and transposition of the great vessels.

**Experimental Production of Congenital Heart Disease.** Congenital heart disease has been produced experimentally by (1) hypoxia in the fetus, (2) vitamin-A deficiency in the mother, (3) deficiency in pteroylglutamic acid in the mother, (4) administration of trypan blue and other azo dyes to the mother, and (5) irradiation of the fetus.

**HYPOXIA.** Many types of anomalies have been produced by hypoxic means, but congenital heart disease was found in only one series (Ingalls et al.). In this series, of 210 pregnant mice suffering hypoxia in 5.5 days of pregnancy, four fetuses showed ventricular septal defect, in three of which it was combined with other abnormalities.

**VITAMIN A DEFICIENCY.** Cardiac anomalies were produced in 28 of 64 newborn rats by vitamin A deficiency in the mother (Wilson and Warkany). The anomalies found were defect of ventricular and aortopulmonary septum and aortic arch malformations. These anomalies could be prevented by administration of vitamin A prior to the twelfth day of pregnancy (Wilson et al., 1953).

**DEFICIENCY OF PTEROYLGLUTAMIC ACID** Deficiency of pteroylglutamic acid in the mother produced the following cardiac anomalies: ventricular septal defects, truncus arteriosus communis persistens, double or right aortic arch, absence of the ductus arteriosus, and aberrant origin of the subclavian arteries (Baird).

**TRYPAN BLUE** The injection of trypan blue into pregnant rats has repeatedly produced congenital anomalies of the heart. The anomalies produced were ventricular septal defect, atrial septal defect, patent ductus, pulmonary stenosis or atresia (Richmann). Other azo dyes, such as Evans blue, Niagara blue 4B, and Niagara blue 6B, have a lesser teratogenic effect (Wilson, 1955).

In one series, the injection of trypan blue produced a pathologic complex consisting of displacement of both atria, elongation of the heart, counterclockwise rotation of the heart, ventricular septal defect, detorsion of the aorta, and pulmonary stenosis. The dye acts probably by altering the maternal metabolism since the dye is not found in the placenta or fetus, but in the reticuloendothelial system of the mother (Fox and Coss).

**IRRADIATION** Irradiation of rat embryos directly through the abdominal incision of the mother caused the following developmental defects: situs inversus, failure of development of the foramen secundum, transposition of the great vessels, right or double aortic arch, truncus communis, atrial and ventricular septal defects, and common AV orifice (Wilson et al., 1953).

**HORMONES.** Although abnormalities have been produced by the administration of ACTH, cortisone (Fraser and Feinstat), and anterior pituitary extract (Fraser and Feinstat), no congenital heart disease has been found to date.

## **PATHOGENESIS**

Although the etiology is obscure, it can be assumed that some factor acts during the first two months of pregnancy to produce an abnormality in the development of the heart. This abnormality may be considered to be purely *embryologic*, or, in addition, a *phylogenetic factor* may be assumed to be operating in the production of some abnormalities. It is therefore essential to introduce the subject with a brief summary of the development of the heart phylogenetically and embryologically.

**Phylogenetic Development of the Vertebrate Heart.** The evolution of the mammalian heart is part of the evolution of the circulation of vertebrates, which is related to the progress of life as it emerged from sea water to fresh water and from fresh water to land. The outstanding characteristics of terrestrial habitat are (1) the presence of a relatively tremendous amount of oxygen in the atmosphere, (2) the low viscosity of the air, permitting rapid motion, (3) the marked fluctuations in temperature, and (4) the relative absence of water. The development of the circulation of vertebrates, although correlated with adaptations to all these environmental factors, was mostly related to the increasing ability to utilize oxygen.

With a change from a water to a land environment, lungs were developed with a gradually increasing amount of respiratory epithelium. This made possible increased absorption of oxygen and increased liberation of carbon dioxide, greater than that possible in gill-bearing vertebrates. This in turn resulted in fundamental changes in the transport of these substances and in the giving of the one and the removal of the other from the body cells. There thus ensued marked changes in the physiology and morphology of the circulation. The physiologic changes were (1) an increased efficiency of the pump, (2) an increase in the oxygen-carrying capacity of the blood, and (3) an increase in oxygen tension. The increased efficiency of the pump was obtained by (1) an increase in pressure, (2) an increase in speed of transmission of the excitation process, (3) an increase in heart rate, and (4) an increase in rate. All these may be said to have been catalyzed mostly by the oxygen in the atmosphere and the circumstances available for its utilization, reinforced by homeothermism in birds and mammals (Clark).

The associated morphologic changes concerned

themselves mostly with the heart. The evolution in cardiac structure in vertebrates involves a change from the single circulation found in the fish with a four-chambered heart, whose chambers are arranged in series, to a double circulation of interchanging blood, found in the bird and mammal with a four-chambered heart, two of whose chambers are arranged in parallel to the other two (Spitzer). This remarkable change is brought about in two phases of development (Pernkopf and Wirtinger)

In the first phase, the straight-tubed heart bends and twists upon itself in the form of an atrioventriculobulbar loop and bayonet-shaped bulb. Concomitant with this is the beginning formation of septa and cushions in the atria and bulb. Thus as far as the development proceeds in the amphibia. In the second phase, the bulb is absorbed into the ventricles. Concomitant with this is the completion of septation, the reorientation of the atria and ventricles, the absorption of the sinus venosus, and the development of valves. In reptiles, this process proceeds only partially, with incomplete septation in the ventricles. In birds and mammals, the complete separation of the circulations occurs.

sible for the initial division of the cardiac tube into sinus venosus, atrium, ventricle, and bulb; the subsequent absorption of the bulb and sinus venosus, and the formation of septa throughout the heart tube (Diagram 6-1) (Spitzer; Lev and Saphir, 1945).

**The Embryologic Development of the Heart.** The human heart arises from paired primordial thickenings in the splanchnic mesoderm, situated lateral to the primitive pharynx. From a proliferation of these cardiogenic plates, cells become separated and form elongated endothelial tubes on each side of the primitive gut. Two constrictions subsequently divide these tubes into three parts: a cephalic or bulbar, a middle or ventricular, and a caudal atrial region. With the formation and separation of the floor of the foregut from the yolk sac, the endothelial tubes swing medialward and progressively fuse ventral to the foregut anteriorly and posteriorly. Above and below this fused endothelial tube, the cardiogenic plates likewise come together, forming the epimyocardial mantle. The fusion of the cardiogenic plates dorsally forms the dorsal mesocardium. No ventral mesocardium is formed in the human embryo. The dorsal mesocardium subsequently disappears, and the heart is now freely suspended in the adjacent primitive coelom, which thus forms the pericardial cavity. At this stage, the heart consists of a tubular structure made up of the following: (1) the bulb, (2) the primitive ventricle, (3) the primitive

<sup>1</sup> See also Part 1, Chap. 1. Editor

atrium, and (4) the sinus venosus. The truncus arises from the bulbus and, at this stage, is connected to the dorsal aorta by the first aortic arches (Arey, Patten, Jordan and Kindred; Hamilton et al.).

The development of the heart from this point may be divided into two phases, as in phylogeny. (1) the formation of the atrioventriculobulbar loop and (2) the absorption of the bulbus (Arey; Patten; Jordan and Kindred; Hamilton et al.; Odgers; Pernkopf and Wirtinger).

**PHASE I** Up to about 7 mm because of the relatively greater growth of the heart than that of the containing cavity, and because its cranial and caudal ends are fixed by the aortic arches and the septum transversum, respectively, the cardiac tube twists upon itself in three dimensions to form the complex atrioventriculobulbar loop (or bulboventricular loop). During this formation, torsions of 90° occur at the atrioventricular and ventriculobulbar orifices in such a way as to approximate their mesocardial walls (Pernkopf and Wirtinger).

At 4 to 5 mm of fetal length, the anlage of the septa begins to be laid down on all portions of the heart tube—the septum primum, the endocardial cushions, the main ventricular septum, the proximal bulbar cushions A and B, the distal bulbar cushions 1 to 4, and the truncus spurs. Although each of these must be dealt with separately, they are all simultaneous parts of the process of septation, related to the formation of the atrioventriculobulbar loop.

**PHASE II.** This phase concerns itself mostly with the *absorption of the bulbus*, but includes the absorption of the sinus venosus and changes in the atrial canal region. According to Pernkopf and Wirtinger, the absorption of the bulbus is affected by two processes. A torsion of 150° (counterclockwise looking truncusward from the bulbus) occurs at the bulbotruncal ostium and a back torsion of about 45° (clockwise looking bulbusward from the ventricle at the ventriculobulbar ostium). These torsions unwind the bulbus and telescope it. This is accompanied by a deviation of the bulbus to the left and ventrally. The changes in the bulbus are associated with simultaneous changes in the atrial canal. This canal shifts to the right and dorsally, so that the bulbus sinks into the groove between the developing mitral and tricuspid valves. In this way, the bulbus is

absorbed into the ventricles, its aortic portion disappearing as a separate entity while its ventral portion assumes the role of conus of the right ventricle. During this phase, septation is completed in all parts of the cardiac tube.

Simultaneous with the absorption of the bulbus occurs the absorption of the sinus venosus and the common pulmonary vein. The *sinus venosus* is divided into right, left, and transverse portions or horns. The left horn early becomes smaller than the right, because of a shift of venous blood from the left to the right side. From 10 to 20 mm, the sinus lags behind the growth of the right atrium so that the right horn is absorbed into the latter. The transverse portion becomes the coronary sinus, while the stem of the vein of Marshall is the only remnant of the left horn. The eustachian and thebesian valves are remnants of the right valve of the sinus venosus. The linea terminalis demarcates that portion of the right atrium arising from the sinus and that portion comprising the primitive right atrium. The absorption of the common pulmonary vein will be dealt with below.

**THE ATRIAL SEPTUM** At 4 to 5 mm, the septum primum appears in the cephalodorsal wall of the primitive atrium growing ventrocaudally. The residual foramen between the resulting atria adjacent to the endocardial cushions is the foramen primum. At 6.5 mm, the dorsal component is met by a small ventral component. Cranially, at 8 to 11 mm, there is a defect in union of these components, with the production of the foramen ovale I. With the fusion of the endocardial cushions, the latter grow to meet the *septum primum*, thus eliminating the *foramen primum* (10 to 12 mm).

The *septum secundum* is likewise developed from dorsal and ventral components (9 to 18 mm). The dorsal is the primordial septum secundum and the left valve of the sinus venosus (possibly including the septum spurium). The ventral is the septum intermedium which is an extension of the fused endocardial cushions. The opening in this septum primum and secundum results in their overlapping and makes possible the closure of the foramen ovale I and II after birth.

The foramen ovale becomes physiologically closed at birth almost instantaneously. It becomes anatomically so by 1 year of age. In about 25 per cent of instances, it may remain

obliquely probe patent. The physiologic closure is probably affected as follows: with the onset of respiration there is a fall in pulmonary pressure and an increase in pulmonary and left atrial flow. The increase in pressure in the left atrium produces the approximation of the overlapping two atrial septa.

**THE MITRAL AND TRICUSPID ORIFICES AND VALVES.** At 4 to 5 mm, the dorsal and ventral endocardial cushions form on the common AV canal. At this stage, this canal is situated to the left of the bulbus. Later (11 mm), right and left lateral endocardial cushions make their appearance. The right lateral cushion is apparently formed from the proximal bulbar swelling B or its junction with the fused anterior and posterior endocardial cushions. At about 11 mm, the anterior and posterior endocardial cushions fuse, forming the mitral orifice and the tricuspid orifice, and about the same time the cushions send an extension up to fuse with the septum primum, obliterating the foramen primum.

The division of the mitral and tricuspid orifices occurs while the entire atrial canal shifts posteriorly and to the right behind the ventrally advancing bulbus. Thus the mitral and tricuspid orifices are formed during the absorption of the bulbus.

The development of the *mitral* and *tricuspid* valves occurs in three periods (Odgers). In the first period (11 to 23 mm), the various leaflets are first derived as follows. The inferior leaflets of the mitral and tricuspid valves are formed from the lateral endocardial cushions (11 mm), the aortic leaflet of the mitral from the fused anterior and posterior cushions (11.4 mm), the anterior leaflet of the tricuspid from the fused anterior and posterior cushions and the right proximal bulbar swelling B (11.4 to 14.5 mm), and the septal cusp of the tricuspid from the posterior endocardial cushion (15.5 mm). During this period, the leaflets consist of cushion material and muscular trabeculae, with the former predominating.

In the second period (23 to 61 mm), muscle gradually invades and replaces cushion material. During this stage, correlated with changes in the *pars membranacea*, the developing tricuspid leaflets migrate to become more distal than the mitral leaflets. In the third period (85 mm to 4 months), collagenous tissue invades the muscle.

**THE VENTRICULAR SEPTUM AND THE AORTA AND PULMONARY ARTERIES AND VALVES.** At 7 mm the main ventricular septum appears, growing upward toward the endocardial cushions. The main septum fuses with the dorsal endocardial cushion to the right of its mid-point by 8 to 9 mm. This leaves a large interventricular foramen.

In the meantime, the aorta and pulmonary artery are developed distally from the left fourth and sixth aortic arches and proximally from the division of the primitive truncus. The latter occurs through the growth of the aortopulmonary septum. This is produced by the fusion of the spurs between the fourth and sixth arches; the septum proceeds caudally as an arched membrane, sending ahead longitudinal ridges as forerunners.

At the same time, the bulbar septum has been developing from distal bulbar swellings 1 and 3 and ridges 1A and 3B (Fernkopf and Wutinger). By 10 mm, the aortopulmonary septum has bisected bulbar swellings 1 and 3, which have fused in their centers. With the absorption of the bulbus, the proximal bulbar septum is developed, and this septum is brought into alignment with the main ventricular septum described above (10 to 20 mm). This leaves a small opening between the ventricles, which is filled in by the endocardial cushions, the bulbar cushions, and perhaps some connective tissue which covers the main muscular ventricular septum to form the *pars membranacea* (15 to 20 mm) (Odgers) (Fig. 6-1).

The peculiar position of the *pars mem-*

Fig. 6-1. Diagrammatic sketch of elements involved in the final closure of the interventricular foramen.

*brancea* between both ventricles, and also between the right atrium and left ventricle, is related to the following (Hamilton et al.). The original fusion of the endocardial cushions occurs somewhat to the left of the mid-point of the cushions. The main ventricular septum joins the posterior endocardial cushion (8 to 9 mm) considerably to the right of the mid-point, while the septum primum meets the fused endocardial cushions to the left of the mid-point (10 to 12 mm). When the *pars membranacea* is thus formed later, a portion of this is relatively horizontal and atrioventricular. Subsequently, this portion becomes vertical and in line with the atrial and ventricular septa.

From the above, it is evident that the definitive *interventricular septum* consists of three components: a posterior septum derived from the main ventricular septum, an anterior septum derived from the bulbar septum, and a membranous septum derived mainly from the endocardial cushions.

The *aortic and pulmonic valves* are fashioned by an undermining process involving distal bulbar cushions 1, 2, 3, and 4. This yields the aortic right and left anterior coronary cusps, and the noncoronary posterior cusp, and the pulmonary right and left posterior cusps, and the anterior cusp. The anterior aortic and posterior pulmonic cusps are derived from cushions 1 and 3, the posterior aortic from cushion 4, and the anterior pulmonic from cushion 2.

**THE SYSTEMIC VEINS.** At 3 mm, there are three series of veins in the embryo: (1) the umbilical veins draining the chorion, (2) the vitelline veins draining the yolk sac, and (3) the cardinal veins draining the embryo itself. The cardinals consist of the precardinals and postcardinals uniting to form the common cardinals, which also drain the vitelline and umbilical veins. Somewhat later, the subcardinals and supracardinals develop, also draining the embryo.

The transformation of the *vitelline and umbilical veins* is related to the development of the liver (4 to 9 mm). The growth of the liver breaks up the vitelline vessels into sinusoids with proximal and distal segments. At the same time, there is a shift of blood to the right horn of the sinus, with an atrophy of the left. The distal segments of the vitelline veins

are converted into the *portal vein*, the intermediate portions remain as the *sinusoids*, while the proximal portions become the *hepatic veins*, which at this stage drain into the right horn of the sinus venosus.

With the further growth of the liver, the developing umbilical veins are rerouted through the hepatic sinusoids. There is now a disappearance of the right and proximal part of the left, with the remainder of the left persisting. A diagonal passage is now dug out through the hepatic sinusoids to form the ductus venosus. Thus at 11 mm, blood passes from the placenta through the umbilical vein through the ductus venosus into the sinus venosus.

The differentiation of the cardinal system into the superior and inferior venae cavae occurs from 4 to 22 mm. These changes are related to the development of the *kidney*. At 4 mm the pre-, post-, and subcardinal veins have developed. By 11 mm, the hepatic portion of the inferior vena cava develops from the vitelline veins, and an anastomosis develops between the subcardinals. At 15 mm the supracardinals develop, and the postcardinal system begins to atrophy. By 22 mm, the inferior vena cava has developed from a fusion of various parts: the vitellines, the subcardinals, and the supracardinals.

At about 20 mm, the *superior vena cava* is developed from the precardinal system as follows. At first, an oblique cross channel (left innominate) is formed, shunting blood from the left vein across to the right. This results in the loss of the communication of the left precardinal just caudad with the left common cardinal. The latter remains as the distal part of the *vein of Marshall*. The right common cardinal and the right precardinal become the superior vena cava. The azygos and hemiazygos are developed from the supracardinals at about 22 mm.

**THE PULMONARY VEIN.** It is generally agreed that the pulmonary vein originates from two sources. (1) a presplanchnic source consisting of a channel formed from the confluence of the vascular plexuses of the lung, which extends to the middle part of the sinus venosus without opening into it, and (2) the main pulmonary stem being an outgrowth from the heart tube. There are two opinions, however, as to whether the latter originates from the

sinus venosus or from the left atrium. The common pulmonary vein is developed at 5 mm.

During the second phase of the development of the heart, concomitant with the absorption of the sinus venosus into the right atrium, the common pulmonary vein is absorbed into the left atrium. This is followed by the absorption of the right and left pulmonary veins, so that definitively four separate pulmonary veins enter the left atrium.

**THE AORTIC ARCHES** The aortic arches make their appearance as follows: first pair, 1.3 mm, second, 3 mm; third, 4 mm, fourth, 5.6 mm; and sixth, 11 mm. These arches form communications between the two dorsal and ventral aortas. At 7 mm, the first and second arches are obliterated. The ventral and dorsal aorta proximal to the third arches persist as the external and internal carotid arteries, respectively. The third arches form the stems of the internal carotid arteries, while the ventral aortas between the third and fourth persist as the common carotids. This is the stage of development at about 10 mm. By 14 mm the dorsal aortas between the third and fourth arches atrophy. Between 14 and 16 mm, the right dorsal aorta between the subclavian and common dorsal aorta likewise is lost. Thus, the fourth left arch and common dorsal aorta now assume the topography of the definitive aorta, and the right fourth remains as the proximal part of the right subclavian (Fig. 6-2). Also at 14 to 16 mm, the right limb of the aortic sac elongates to form the innominate artery.

The distal portion of both subclavian arteries and the proximal part of the left develop from the seventh segmental arteries. Throughout their development, these derivatives undergo a constant cranial migration from their position low down on the fourth arches. Because of the difference in derivation of the two vessels, the left ascends more than the right. At about 16 mm, the left subclavian is just distal to the ductus arteriosus. Subsequently, it assumes its definitive position proximal to the isthmus. The right sixth aortic arch remains as the right pulmonary artery, while the left persists as the left pulmonary artery and ductus arteriosus.

**THE CORONARY ARTERIES.** These vessels begin as thickenings of the aortic endothelium at 10 to 12 mm of fetal length. This is also

Fig. 6-2. Transformation of the human aortic arches (ventral view). Scheme with the dorsal vessels spread lateral, to show persisting vessels (black), discontinued vessels (white), and atrophic vessels (stipple) (From Aray. *Developmental Anatomy*. Saunders, 1954)

the time the truncus septum is bisecting the larger pair of the distal bulbar swellings, which have fused in their centers. Both coronary arteries pass to the sides of the bulbous cordis, and the anterior descending coronary artery begins to be laid down. By 14 mm both circumflexes are developed, and by 20 mm all larger branches are developed.

**THE CONDUCTING SYSTEM.**<sup>2</sup> There is a difference of opinion as to the method of development of the sinoatrial node. According to some (Walls), it can be recognized at 7 to 10 mm and is derived from sinus venosus musculature. According to others (Shaner), it appears as a new formation at 100 mm on the ventrolateral surface of the superior vena cava.

The atrioventricular node is a derivative of the AV ring, being seen at 8 to 9 mm, at a time when the ring is still complete. It lies behind the posterior endocardial cushion. The bundle and the beginning of the left branch are recognized at about the same time and may be developed in situ or as outgrowths from the AV node. By 13 mm, the right bundle appears as a similar growth, and by 22 to 25 mm the right limb can be traced into the moderator band.

Nerve fibers appear in the region of the SA and AV nodes at about 21 mm.

<sup>2</sup> See also Part I, Chap. 5, Editor.

branacea between both ventricles, and also between the right atrium and left ventricle, is related to the following (Hamilton et al.). The original fusion of the endocardial cushions occurs somewhat to the left of the mid-point of the cushions. The main ventricular septum joins the posterior endocardial cushion (8 to 9 mm) considerably to the right of the mid-point, while the septum primum meets the fused endocardial cushions to the left of the mid-point (10 to 12 mm). When the pars membranacea is thus formed later, a portion of this is relatively horizontal and atrioventricular. Subsequently, this portion becomes vertical and in line with the atrial and ventricular septa.

From the above, it is evident that the definitive *interventricular septum* consists of three components: a posterior septum derived from the main ventricular septum, an anterior septum derived from the bulbar septum, and a membranous septum derived mainly from the endocardial cushions.

The *aortic and pulmonic valves* are fashioned by an undermining process involving distal bulbar cushions 1, 2, 3, and 4. This yields the aortic right and left anterior coronary cusps, and the noncoronary posterior cusp, and the pulmonary right and left posterior cusps, and the anterior cusp. The anterior aortic and posterior pulmonic cusps are derived from cushions 1 and 3, the posterior aortic from cushion 4, and the anterior pulmonic from cushion 2.

**THE SYSTEMIC VEINS.** At 3 mm, there are three series of veins in the embryo (1) the umbilical veins draining the chorion, (2) the vitelline veins draining the yolk sac, and (3) the cardinal veins draining the embryo itself. The cardinals consist of the precardinals and postcardinals uniting to form the common cardinals, which also drain the vitelline and umbilical veins. Somewhat later, the subcardinals and supracardinals develop, also draining the embryo.

The transformation of the *vitelline and umbilical veins* is related to the development of the liver (4 to 9 mm). The growth of the liver breaks up the vitelline vessels into sinusoids with proximal and distal segments. At the same time, there is a shift of blood to the right horn of the sinus, with an atrophy of the left. The distal segments of the vitelline veins

are converted into the *portal vein*, the intermediate portions remain as the *sinusoids*, while the proximal portions become the *hepatic veins*, which at this stage drain into the right horn of the sinus venosus.

With the further growth of the liver, the developing umbilical veins are rerouted through the hepatic sinusoids. There is now a disappearance of the right and proximal part of the left, with the remainder of the left persisting. A diagonal passage is now dug out through the hepatic sinusoids to form the *ductus venosus*. Thus at 11 mm, blood passes from the placenta through the umbilical vein through the *ductus venosus* into the sinus venosus.

The differentiation of the cardinal system into the superior and inferior venae cavae occurs from 4 to 22 mm. These changes are related to the development of the *kidney*. At 4 mm the pre-, post-, and subcardinal veins have developed. By 11 mm, the hepatic portion of the inferior vena cava develops from the vitelline veins, and an anastomosis develops between the subcardinals. At 15 mm the supracardinals develop, and the postcardinal system begins to atrophy. By 22 mm, the inferior vena cava has developed from a fusion of various parts: the vitellines, the subcardinals, and the supracardinals.

At about 20 mm, the *superior vena cava* is developed from the precardinal system as follows. At first, an oblique cross channel (left innominate) is formed, shunting blood from the left vein across to the right. This results in the loss of the communication of the left precardinal just caudad with the left common cardinal. The latter remains as the distal part of the *vein of Marshall*. The right common cardinal and the right precardinal become the superior vena cava. The azygos and hemiazygos are developed from the supracardinals at about 22 mm.

**THE PULMONARY VEIN.** It is generally agreed that the pulmonary vein originates from two sources. (1) a presplanchnic source consisting of a channel formed from the confluence of the vascular plexuses of the lung, which extends to the middle part of the sinus venosus without opening into it, and (2) the main pulmonary stem being an outgrowth from the heart tube. There are two opinions, however, as to whether the latter originates from the

forms of the mammal. This detorsion brings about the reopening of the right ventricular aorta. The aorta in the anomaly overriding aorta is thus connected with the conus of both the right and left aorta, while in partial and complete transposition, there is obliteration of the left ventricular aortic conus and persistence of the right ventricular aortic conus.

In a study of the development of the heart in the bird, Bremer suggested the interpretation that the crossing of the circulations is achieved not in the bulbus, but in the atrial region. He, therefore, suggested that complete transposition was due to the lack of formation of a kink in the atrial region, thus producing a torsion of only  $90^\circ$  instead of  $270^\circ$  in this region. This puts the pulmonary vein into the dorsal and the vena cava into the ventral portion of the heart tube. The remainder of the heart tube itself is deprived of  $180^\circ$  torsion, and the bulbus is not kinked. Thus, the aorta becomes connected with the dorsal part of the heart tube. Partial transposition is due to the failure of development of the basal part of the interventricular septum and the abnormal deviation of the remainder of the septum. This places the aorta into the right ventricle.

Pernkopf and Wirtinger concluded that the abnormality lay in the construction of a straight bulbar septum, due to the primary development of straight ridges between the bulbotruncal ostium and the ventriculobulbar ostium. The incorporation of a bulbus with such ridges into the ventricles is not accompanied by the normal torsion at the bulbotruncal ostium, and therefore the aorta and pulmonary artery are transposed. Brecht considered the dextroposition of the aorta in tetralogy of Fallot the result of the septal defect. Since the wall of the aorta has no support on the right side, it widens in this direction. The pulmonary stenosis is an independent anomaly and has the same etiology as pulmonary stenosis without ventricular septal defect. Lev and Saphir postulated that transposition of the arterial trunks is due to an abnormality in the absorption of the bulbus, as claimed by Keith. It is thus an abnormality in the execution of the second phase of the development of the heart. Instead of the normal torsion of  $150^\circ$  occurring at the distal ostium and the minimal back torsion occurring at the proximal ostium, here is an increased back torsion at the prox-

imal ostium. This eliminates the necessity of torsion at the distal ostium, which is either diminished or completely absent. The underlying abnormality in the proximal bulbar ostium, which permits the increased back torsion, is an abnormality in the bulbotruncal spur area. The center of this area should constitute a fixed point in development about which the bulbus and atrial canal rotate. Where the intimacy between the bulbus and atrial canal is not established, the proximal end of the bulbus in the process of its absorption is capable of back torsion in the elimination of the twist of the bulbar ridges. This produces various positions of the aorta and the pulmonary artery. Lev and Saphir (1945) suggested an alternate etiology for the assumed abnormal absorption of the bulbus. They suggested that an abnormality in the formation of ridge 3B, whereby it takes on the course of the reptilian ridge 4B or 3C, may be responsible both for the abnormal absorption of the bulbus and for the unequal division of the aorta and pulmonary artery and their conus.

A new approach to the problem was begun by Shaner (1949). He studied early malformed pig embryos which still retained embryonic landmarks to find a clue for malformations. In abnormal pig embryos with overriding aorta (tetralogy of Fallot), he found evidence of abnormality in the development and absorption of the bulbus, due to defective development of the endocardial cushions, especially the insufficient excavation of the anterior. This prevents the proper migration of the aortic orifice to the left ventricle, thus producing an overriding aorta. The pulmonary artery may be compressed between the crista supraventricularis and the ventricular wall to produce pulmonary or conus stenosis. Doerr applied this theory to overriding aorta in man.

Vosenaar, likewise, following the work of Keith, Lev and Saphir, and Shaner, considered tetralogy of Fallot an abnormality in the incorporation of the bulbus into the ventricles. This may be due to (1) insufficient development of a portion of the wall of the bulbus cordis, (2) insufficient or delayed excavation of the inferior side of the anterior endocardial cushion, (3) insufficient or delayed reduction of the bulbotruncal crest, or (4) insufficient development of the dextrodorsal bulbar cushion B and ridge 3B. De la Cruz and Pio da Rocha

CLOSURE OF THE DUCTUS ARTERIOSUS.<sup>3</sup> The method of normal closure of the ductus is not clearly understood. It is in some way or other related to the onset of respiration. The latter results in a fall in pulmonary resistance and an increase in pulmonary flow. This is associated with an increase in left ventricular flow and in systemic pressure. Thus, blood is drawn away from the muscular ductus, which contracts and becomes nonfunctioning within minutes after birth. It becomes anatomically closed by 3 months of age.

*Pathogenesis of Individual Abnormalities.* Most abnormalities are best explained on the basis of an arrest in embryologic development or abnormal embryologic development. Some abnormalities likewise may be considered as secondary hemodynamic consequences of other abnormalities. In transposition of the arterial trunks, a phylogenetic variant may be invoked, acting during embryologic development.

**TRANSPPOSITION OF THE ARTERIAL TRUNKS**  
The term "transposition" as used here means an abnormality in the position of the aorta and the pulmonary artery with respect to each other or with respect to the chambers from which they emerge. Hence, this term includes overriding aorta, partial transposition, Taussig-Bing heart, and complete transposition. In *overriding aorta*, the aorta emerges from both ventricles, while the pulmonary artery emerges from the right ventricle. In *partial transposition*, both vessels emerge from the right ventricle. In *overriding pulmonary artery*, the aorta emerges from the right, while the pulmonary artery emerges from both ventricles. In *complete transposition*, the aorta emerges from the right, while the pulmonary artery emerges from the left ventricle.

The embryogenesis of transposition complexes has intrigued embryologists, anatomists, and pathologists for many years. Peacock and others, in *tetralogy of Fallot*, considered the stenosis (due to fetal endocarditis) to be primary. The increased right ventricular pressure resulted in a defect of the ventricular septum and displaced the interventricular septum to the left. This forced the aorta to emerge from the right ventricle. Meckel considered the septal defect to be primary. This causes the aorta of necessity to arise from both ventricles

or the right ventricle. The flow of blood through the aorta results in a deviation of the stream from the pulmonary artery, and hence the stenosis. Rokitsky considered the stenosis and defect secondary to transposition and all types of transposition due to a common abnormality in the septum trunci. An overriding aorta is produced by a parallel deviation of the truncus septum to the left. This results in *pulmonary stenosis*. Because of the inability of the ventricular septum to meet the misplaced bulbar septum, a defect in the former results. The other types of transposition are produced by various degrees of abnormal rotation of the septum trunci, resulting in its abnormal relationship to the ventricular septum, thus placing either one or both vessels in the wrong ventricles. This fundamental work was enlarged upon with variation by succeeding authors. Keith suggested that transposition was due to the abnormal absorption of the bulbus into the ventricles. Normally, the aortic portion should atrophy, while the pulmonary portion expands. In transposition, the reverse occurs, placing the aorta ventrally and into the right ventricle, with the pulmonary artery in the left.

Spitzer (1923) evolved a phyloontogenetic theory of transposition based on his theory of the normal development of the heart. In his opinion, transposition of the arterial trunks is due to a phylogenetic abnormality reinforced by ontogenetic and hydrodynamic factors. In his view, in the mammalian heart, there are certain "atavistic" structures, that is, structures similar to those found in the ancestral tree, but which are present only in rudimentary form in the mammalian heart. These are (1) a remnant of the obliterated right ventricular aorta of the reptile and (2) the crista supraventricularis. In transposition, Spitzer theorizes that there is an abnormality in ontogenesis which permits an arrest in development in the particular case at a lower phylogenetic level. This results in a reawakening and development of the atavistic features present in the mammal and the coordination of these features with those already attained by the mammal.

The reactions are set off by some unknown stimulus, resulting in a lack of the usual amount of mammalian torsion (*detorsion*) of the cardiac tube or the presence of the amount of torsion present in the ancestral reptilian

<sup>3</sup> See also Part 1, Chap. II Editor.

tricle. In defects associated with tricuspid atresia or pulmonary stenosis with normal aortic root, the defects may be considered as secondary hemodynamic effects created by an increase in pressure on the left or right side, resulting in a lack of completion of the pars membranacea and the surrounding anterior and posterior parts of the ventricular septum.

In transposition complexes, the ventricular septal defects are due to the lack of formation of the proximal bulbar septum, which is a concomitant of malabsorption of the bulbus, reinforced by the above hemodynamic effects. These effects may result in defective formation of the posterior ventricular septum as well, producing the large defects or complete absence of the ventricular septum.

**PULMONARY STENOSIS, ATRESIA, AND HYPOPLASIA.** The pulmonary hypoplasia, which is associated with transposition, may be explained by the uneven division of the bulbus during its malabsorption. The true valvular stenosis of isolated pulmonary stenosis or pulmonary stenosis with defects, or that found in the uncommon case of tetralogy of Fallot, cannot be readily explained either as an inhibition or as an abnormal development. Perhaps it can be explained as a secondary hemodynamic effect. It is here that fetal endocarditis still remains a possibility.

**AORTIC STENOSIS OR ATRESIA.** In supravalvular aortic stenosis, there may be an exaggeration of the ridge formation normally found in the upper margins of the sinuses of Valsalva of the aorta. Aortic stenosis, where the involvement is basically in the valve, is difficult to explain as an embryologic variant, and hemodynamic phenomena secondary to abnormal valve formation or a fetal endocarditis may be postulated. In hypoplasia of the aortic tract complex with aortic stenosis or atresia, the latter may be considered secondary hemodynamic effects of decreased flow.

**TRUNCUS ARTERIOSUS COMMUNIS PERSISTENS.** In this anomaly, there is failure of development of the aortopulmonary septum, due to lack of formation and fusion of the spurs between the fourth and sixth arches. This is usually associated with malabsorption of the bulbus, hence the origin of the truncus in a riding position or from the right ventricle.

**AORTOPULMONARY SEPTAL DEFECT.** Such a defect may be explained as an embryologic

lack of fusion of the septum aortopulmonale with the distal bulbar cushions 1 and 3.

**HYPOPLASIA OF THE AORTIC TRACT COMPLEXES.** There are at least three possible embryologic variants in this group of anomalies: (1) There may be hypoplasia of the fourth left arch, with a corresponding unequal division of the truncus by the spurs between the fourth and sixth arches. (2) There may be a lessened flow of the inferior vena caval blood through the foramen ovale into the left side during embryologic life. In the latter case, there may be an abnormality in the approximation of the septum primum and secundum. (3) There may be an abnormally large ductus arteriosus, perhaps related to increased pulmonary resistance and lessened pulmonary flow. Thus, the left side is anatomically hypoplastic to a varying extent, and the right side is anatomically hyperplastic just before birth. This represents an exaggeration of the normal condition. Where the complex includes mitral atresia or stenosis, the latter may be considered to be hemodynamically produced because of lack of or altered flow.

**COARCTATION OF THE AORTA.** The infantile (preductal) and the adult (postductal) types apparently have a different genesis. In the former, there is a hypoplasia of the fourth left arch, between the origin of the subclavian (or even more proximally) and the entry of the ductus arteriosus, which is always widely patent. This segment in the fetus has less flow than the ascending or descending aorta. Thus, as in hypoplasia of the aortic tract complexes, the primary abnormality may be the hypoplasia of the fourth left arch, or the other factors mentioned in hypoplasia of the aortic tract.

The pathogenesis of the adult (postductal) coarctation is unknown. It is apparently related to the manner in which the ductus arteriosus enters the aorta and the manner of its partial or complete closure. It is possible that fibrotic shortening and closure of the ductus exerts a pull and angulation upon the aorta or actually involves the latter in its fibrotic metamorphosis.

**ABNORMAL AORTIC ARCHES AND BRACHIOCEPHALIC VESSELS.** In double aortic arch, both fourth arches persist in their entirety, keeping their communication with the dorsal aorta. In a right aortic arch with a left diverticulum, the right fourth arch persists as the aorta, while the

thought that overriding aorta and all types of truncoconal anomalies are related to (1) delay in disappearance of the conoventricular flange (spur), (2) complete or incomplete lack of rotation of the truncoconal septum, (3) unequal partitioning of the truncoconus, (4) defects in growth of the truncoconal ridges, and (5) total or partial absence of the aortic and pulmonary semilunar primordia, fusion or increased number of primordia. Each or any combination of these may occur.

**STENOSIS OF THE LOWER BULBAR ORIFICE.** This anomaly may be considered as an abnormality in the final fusion of the conus of the pulmonary artery with the right ventricle after the absorption of the bulbus. This may occur without an abnormality in the absorption of the bulbus (conus stenosis without transposition) or with such an abnormality (transposition with conus stenosis).

**SUBAORTIC STENOSIS.** Here we may postulate that the final absorption of the bulbus and fusion of the conus of the left ventricle with the left ventricle proper occurs poorly. This may be considered a counterpart of stenosis of the lower bulbar orifice on the right side.

**ATRIAL SEPTAL DEFECTS.** *Patent Foramen Primum.* This represents the persistence of a fetal condition and may be ascribed to (1) a failure of upward extension of the fused endocardial cushions, (2) a failure of fusion of the dorsal and ventral endocardial cushions, or (3) an inhibition of growth of the septum primum.

*Patent Foramen Ovale (Secundum Type)* This anomaly, in the primary form, may be due to a greatly enlarged foramen ovale I or II or both, that is, a lack of growth and hence an overlapping of the septum primum and secundum. As a complication of other abnormalities, the foramen ovale may remain patent because of increased pressure on the right or the left side of the atrial septum.

**COMMON ATRIOVENTRICULAR ORIFICE.** This represents a persistence of the fetal condition, brought about by a lack of fusion of the anterior and posterior endocardial cushions. Because of this lack of fusion, endocardial material does not extend upward to close the foramen primum, and none descends to close the interventricular foramen.

**TRICUSPID AND MITRAL STENOSIS OR ATRESIA.** These anomalies are due to an abnormality in

the fusion of the anterior and posterior endocardial cushions and in the subsequent growth of the resultant mitral and tricuspid orifices. In *tricuspid atresia* or *stenosis* without transposition, this orifice may be encroached upon as the atrial canal moves posteriorly and to the right, during the second phase of the development of the heart. The expansion and definitive position of this orifice is fundamentally dependent upon this movement. *Mitral stenosis* and *atresia* without transposition, however, are better explained as secondary anomalies due to altered hemodynamics, resulting in hypoplasia of the aortic tract complexes, as described below. In *complete transposition with tricuspid or mitral atresia*, there is a combined abnormality in the absorption of the bulbus and in the concomitant division of the atrial canal and its shift to the right and posteriorly behind the bulbus. The abnormally absorbed bulbus, with its resultant transposed vessels, may abut against the mitral and tricuspid orifices, producing a narrowing or atresia. As the realignment of the bulbus and atrial canal may not occur at all, there may be a lack of fusion of the endocardial cushions, leaving a common AV orifice to one side of the transposed arteries (complete transposition with common AV orifice).

**EBSTEIN'S ANOMALY.** Two possibilities present themselves as embryologic variants in this anomaly. (1) The right proximal bulbar cushion may join the fused endocardial cushions to form the lateral cushion as in the normal, but this cushion may hang down more distally than normal into the ventricle. This gives rise to the displaced anterior and inferior leaflets. (2) There may be greater than normal downward displacement of the cushion materials during their distal migration in the second phase of the development of the valves.

**DEFECTS OF THE VENTRICULAR SEPTUM.** In the usual isolated small septal defect (*maladie de Roger*), there is probably a lack of growth of the fused endocardial cushions, or perhaps the bulbar cushions, with resultant failure finally to close the interventricular foramen after the normal absorption of the bulbus (Fig 6-1). Thus, the defect is in the *pars membranacea* and between it and the anterior septum. In a *high septal defect*, there is defective formation of the bulbar septum. Hence, the defect opens into the conus of the right ven-

# Pathology of congenital heart disease

MAURICE LEV

## GENERAL CONSIDERATIONS

The pathology of congenital heart disease is best considered in relation to the myocardium and endocardium. Within the myocardium, hypertrophy or atrophy is the outstanding change seen. Occasionally, in isolated types of anomalies, fibrosis may be encountered. In the endocardium, only *endocardial hypertrophy* (fibroelastosis) and *sclerosis* will be discussed.

Hypertrophy of the myocardium is best described as that related to (1) contraction on an increased volume (which might be called volume hypertrophy), (2) contraction against in-

creased resistance (which might be called pressure hypertrophy) (Abbott, 1927; Edwards, 1953; Rokitsansky; Taussig, 1938).

Thus, this category of anomalies includes those conditions where the aorta emerges from both ventricles or from the right ventricle alone and the pulmonary artery springs from the right or left or both ventricles. Also included are those conditions of mutually abnormally situated arterial vessels arising from a common or slightly subdivided ventricle. Likewise, conditions of truncus communis, truncus solitarius aorticus and pulmonalis fall into this category, where the aortic vessel or component emerges from the right or both ventricles.

Thus, transposition of the arterial trunks, following and expanding Rokitsansky's concepts, may best be classified as follows: (1) *overriding aorta*, (2) *partial transposition*, (3) *overriding pulmonary artery*, and (4) *complete transposition*. In *overriding aorta*, the aorta emerges from both ventricles, while the pulmonary artery emerges from the right. In *partial transposition*, both the aorta and the pulmonary artery emerge from the right ventricle. In *overriding pulmonary artery* (Taussig-Bing heart), the pulmonary artery arises from both ventricles, while the aorta emerges from the right ventricle. In *complete transposition*, the aorta emerges from the right while the pulmonary artery emerges from the left ventricle.

Thus transposition complexes in normal levocardia may be classified as shown below.

### A. Overriding aorta

- 1 With aneurysm of the pars membranacea
- 2 With pulmonary tract hypoplasia (tetralogy of Fallot)

as utilized in the discussion of pathogenesis of the complexes.

Congenital malformations of the heart have a tendency to be arranged in certain pathologic patterns or complexes (Lev, 1953). These are of two types: (1) a group of anomalies may be constantly found associated, and (2) a single anomaly may produce a constant pathologic picture. Our discussion of the pathology of congenital heart disease will thus be centered about the discussion of pathologic complexes, rather than on individual anomalies.

## TRANSPOSITION COMPLEXES

Transposition of the great arterial trunks, according to Abbott, is that condition in which the great trunks have undergone an alteration in their relative positions to each other, or to the ventricles from which they emerge, whereby the aorta comes to be in the path of the un-

left fourth remains only in part as a diverticulum, giving off the subclavian. In *right aortic arch with left descending aorta*, the right fourth arch persists and is pulled over by an aberrant left ductus or the left subclavian. Where the *right subclavian arises from the descending aorta*, there is persistence of the right dorsal aorta between the subclavian and common dorsal aorta, accompanied by an atrophy of its proximal portion. The various *anomalies of the left subclavian*, such as origin from the ductus, from the pulmonary, or from the aorta distal to the ductus, are related to various stages in arrest in the proximal migration of the subclavian.

**ORIGIN OF A CORONARY ARTERY FROM THE PULMONARY ARTERY.** In this anomaly, one of two embryologic variants is possible. (1) Either the primordial thickenings of the coronary arteries are laid down on the wrong side of the junction of the aortopulmonary septum with the distal bulbar cushions, or (2) the septum meets these ridges in an aberrant manner.

**PATENT DUCTUS ARTERIOSUS** The pathogenesis of patent ductus arteriosus is unknown. It may be related to abnormal angle of entry into the aorta, abnormal pulmonary factors initiated with respiration, or persistent large flow. The pulmonary factors may be purely anatomic or hemodynamic. Hemodynamic factors might be represented by too great a fall in pulmonary pressure upon initiation of respiration with resultant left-to-right flow through the ductus, or too small a fall, with persistent right-to-left shunt.

**LEFT SUPERIOR VENA CAVA** This results from the retention of the communication of the left

precordial with the left common cardinal vein.

**ENTRY OF THE PULMONARY VEINS INTO THE SYSTEMIC CIRCUIT.** The following possibilities present themselves as embryologic variants in this anomaly: (1) The presplanchnic channels, instead of uniting with an outgrowth from the cardiac tube, effect a union with any of the following: (a) the precardinal veins (entry of the pulmonary veins into the right or left superior vena cava); (b) the post-, supra-, or subcardinal veins (entry into the inferior vena cava or azygos); (c) the vitelline-umbilical venous systems (entry into the portal vein); (d) the right horn of the sinus venosus (entry into the right atrium); or (e) the transverse horn of the sinus venosus (entry into the coronary sinus). (2) There may be an abnormality of the septum primum.

**ABNORMAL RELATIONSHIP OF CARDIAC CHAMBERS.** The pathogenesis of these abnormalities is not understood. In *mirror-image dextrocardia*, the AV loop curves in an opposite direction than normal. In *pivotal dextrocardia*, the normally formed AV loop is rotated in the horizontal plane to the right. *Mixed dextro- and leio-cardia*, where the atria and ventricles do not correspond, has no ready explanation.

**CONGENITAL ABNORMALITIES IN THE CONDUCTION SYSTEM** The abnormalities in direction, such as in patent foramen primum, common AV orifice, ventricular septal defect, cor biatriatum triloculare, and cor triloculare biventriculosum, are related to a shift in direction posteriorly of the AV node, the AV bundle, or both, due to the defects. Abnormalities in continuity are usually related to fibrotic metamorphosis around the defects.

## GENERAL CONSIDERATIONS

The pathology of congenital heart disease is best considered in relation to the myocardium and endocardium. Within the myocardium, hypertrophy or atrophy is the outstanding change seen. Occasionally, in isolated types of anomalies, fibrosis may be encountered. In the endocardium, only endocardial hypertrophy (fibroelastosis) and sclerosis will be discussed.

Hypertrophy of the myocardium is best described as that related to (1) contraction on an increased volume (which might be called volume hypertrophy), (2) contraction against increased peripheral resistance (which might be called pressure hypertrophy), and (3) ischemia (ischemic hypertrophy). This terminology will be utilized in the discussion of pathogenesis of the complexes.

Congenital malformations of the heart have a tendency to be arranged in certain pathologic patterns or complexes (Lev, 1953). These are of two types. (1) a group of anomalies may be constantly found associated, and (2) a single anomaly may produce a constant pathologic picture. Our discussion of the pathology of congenital heart disease will thus be centered about the discussion of pathologic complexes, rather than on individual anomalies.

## TRANSPOSITION COMPLEXES

Transposition of the great arterial trunks, according to Abbott, is that condition in which the great trunks have undergone an alteration in their relative positions to each other, or to the ventricles from which they emerge, whereby the aorta comes to lie in the path of the un-

aerated blood from the right ventricle (Abbott, 1937; Edwards, 1953; Rokitsansky, Taussig, 1938).

Thus, this category of anomalies includes those conditions where the aorta emerges from both ventricles or from the right ventricle alone and the pulmonary artery springs from the right or left or both ventricles. Also included are those conditions of mutually abnormally situated arterial vessels arising from a common or slightly subdivided ventricle. Likewise, conditions of truncus communis, truncus solitarius aorticus and pulmonalis fall into this category, where the aortic vessel or component emerges from the right or both ventricles.

Thus, transposition of the arterial trunks, following and expanding Rokitsansky's concepts, may best be classified as follows: (1) overriding aorta, (2) partial transposition, (3) overriding pulmonary artery, and (4) complete transposition. In overriding aorta, the aorta emerges from both ventricles, while the pulmonary artery emerges from the right. In partial transposition, both the aorta and the pulmonary artery emerge from the right ventricle. In overriding pulmonary artery (Taussig-Bing heart), the pulmonary artery arises from both ventricles, while the aorta emerges from the right ventricle. In complete transposition, the aorta emerges from the right while the pulmonary artery emerges from the left ventricle.

Thus transposition complexes in normal levocardia may be classified as shown below.

### A. Overriding aorta

1. With aneurysm of the pars membranacea
2. With pulmonary tract hypoplasia (tetralogy of Fallot)

left fourth remains only in part as a diverticulum, giving off the subclavian. In *right aortic arch with left descending aorta*, the right fourth arch persists and is pulled over by an aberrant left ductus or the left subclavian. Where the *right subclavian arises from the descending aorta*, there is persistence of the right dorsal aorta between the subclavian and common dorsal aorta, accompanied by an atrophy of its proximal portion. The various *anomalies of the left subclavian*, such as origin from the ductus, from the pulmonary, or from the aorta distal to the ductus, are related to various stages in arrest in the proximal migration of the subclavian.

**ORIGIN OF A CORONARY ARTERY FROM THE PULMONARY ARTERY** In this anomaly, one of two embryologic variants is possible: (1) Either the primordial thickenings of the coronary arteries are laid down on the wrong side of the junction of the aortopulmonary septum with the distal bulbar cushions, or (2) the septum meets these ridges in an aberrant manner.

**PATENT DUCTUS ARTERIOSUS** The pathogenesis of patent ductus arteriosus is unknown. It may be related to abnormal angle of entry into the aorta, abnormal pulmonary factors initiated with respiration, or persistent large flow. The pulmonary factors may be purely anatomic or hemodynamic. Hemodynamic factors might be represented by too great a fall in pulmonary pressure upon initiation of respiration with resultant left-to-right flow through the ductus, or too small a fall, with persistent right-to-left shunt.

**LEFT SUPERIOR VENA CAVA** This results from the retention of the communication of the left

precardinal with the left common cardinal vein.

**ENTRY OF THE PULMONARY VEINS INTO THE SYSTEMIC CIRCUIT.** The following possibilities present themselves as embryologic variants in this anomaly: (1) The presplanchnic channels, instead of uniting with an outgrowth from the cardiac tube, effect a union with any of the following: (a) the precardinal veins (entry of the pulmonary veins into the right or left superior vena cava); (b) the post-, supra-, or subcardinal veins (entry into the inferior vena cava or azygos); (c) the vitelline-umbilical venous systems (entry into the portal vein); (d) the right horn of the sinus venosus (entry into the right atrium); or (e) the transverse horn of the sinus venosus (entry into the coronary sinus). (2) There may be an abnormality of the septum primum.

**ABNORMAL RELATIONSHIP OF CARDIAC CHAMBERS.** The pathogenesis of these abnormalities is not understood. In *mirror-image dextrocardia*, the AV loop curves in an opposite direction than normal. In *pivotal dextrocardia*, the normally formed AV loop is rotated in the horizontal plane to the right. *Mixed dextro- and levocardia*, where the atria and ventricles do not correspond, has no ready explanation.

**CONGENITAL ABNORMALITIES IN THE CONDUCTION SYSTEM** The abnormalities in direction, such as in patent foramen primum, common AV orifice, ventricular septal defect, cor biatriatum triloculare, and cor triloculare biventriculosum, are related to a shift in direction posteriorly of the AV node, the AV bundle, or both, due to the defects. Abnormalities in continuity are usually related to fibrotic metamorphosis around the defects.

defect is usually situated in the basal part of the anterior portion of the ventricular septum and is of varying size. It usually opens below the deviated crista into the right ventricle, but may pass through the crista. The pulmonary tract is narrowed in the region of the conus, in that of the pulmonic valve, or in both. The usual narrowing is in the conus. A contribution to this narrowing is the abnormality in the crista supraventricularis.

In this anomaly, the septal band of the crista, which may be single or double, is hypertrophied. The mural band is deviated anteriorly, away from the conal tract. The septal band may be divided by the defect, so that only a small band of muscle separates the aorta and pulmonary artery. This conal narrowing may be further reinforced by fibroelastosis.

The right ventricle is hypertrophied, but is usually thinner than the left ventricle. The left atrium and ventricle vary in size from normal to smaller than normal. The tricuspid valve may show varying degrees of mitralization, that is, the medial leaflet may be connected to papillary muscles or may be fused with the anterior or the inferior leaflet. The coronary ostia may be rotated in a counterclockwise manner, looking from the aorta downward into the ventricle. In some cases of tetralogy, the left ventricle is also hypertrophied. When associated with an atrial septal defect, the anomaly has been called a pentalogy.

**PATHOGENESIS OF THE COMPLEX** The basic anomaly may be considered to be the overriding aorta and hypoplastic conus and pulmonary tree (see Chap 1). The ventricular septal defect may be explained on two bases: (1) the abnormal absorption of the bulbus places the bulbar septum out of alignment with the main ventricular septum, (2) the closure of the ventricular septum occurs late in devel-

Fig 6-5. Diagrammatic sketch of blood flow in tetralogy of Fallot (From M. Lev, *Autopsy Diagnosis of Congenitally Malformed Hearts*, Charles C Thomas, 1953).

presents a "pressure hypertrophy" for this chamber contracts against the systemic resistance through the aorta and the increased pulmonary tract resistance. Where the defect is large and the pulmonary stenosis moderate or mild, there may be left-to-right shunt through the defect (cyanotic tetralogy), and the right ventricle may have an increment of volume hypertrophy. It is in these cases, perhaps, that the left ventricle is also hypertrophied.

The blood flow in the usual case of tetralogy of Fallot is as follows (Fig 6-5). The systemic venous flow enters the right atrium and ventricle normally. From the right ventricle, blood flows into the aorta and pulmonary artery. A decreased volume of aerated blood enters the left atrium and ventricle, and from there flows into the aorta.

**Overriding Aorta with Aortic Hypoplasia (Eisenmenger's Complex).** In this anomaly (Saphir and Lev, Selzer and Laqueur, Tausig and Semans), a straddling hypoplastic aorta

ventricular foramen to remain open. The deviation of the crista, if not explained by Spitzer's theory, may be related to the flow pattern set up by the ventricular septal defect. The crista

**Overriding Aorta with Aneurysm of the Pars Membranacea.** In this anomaly (Lev and Saphir, 1937), the aorta straddles the muscular ventricular septum over an aneurysm of the *pars membranacea* (Fig. 6-3). The aorta emerges, however, only from the left ventricle, and hence, strictly speaking, this is not a transposition complex. The aneurysm bulges into the right atrium, right ventricle, or both. The muscle bundles of the right ventricle may be normal, or the parietal band of the crista may be shortened and slightly deviated anteriorly and to the left, with an abrupt termination. The aneurysm may be associated with deformity of the aortic valve, with or without aortic regurgitation, or there may be secondary changes in the atrioventricular bundle with AV block, or there may be a secondarily produced ventricular septal defect. The aneurysm may bulge into the tricuspid orifice, impeding its function.

**Overriding Aorta with Pulmonary Tract Hypoplasia (Tetralogy of Fallot).** In this anomaly (Rowe et al., Vossenaar), a large aorta straddles the interventricular septum over a defect of the latter, thus emerging to a varying extent from both ventricles (Fig. 6-4). The

Fig. 6-4. Tetralogy of Fallot. A. Anterior view. B. View looking into the ventricular septal defect from the right side. C, crista; D, defect; A, aorta; P, pulmonary artery.

A true Eisenmenger complex, from the pathologic standpoint, can be differentiated from ventricular septal defect by the abnormal architecture of the muscle bundles of the right ventricle. However, a distinction must be made between the Eisenmenger syndrome, clinically, and the morphologic findings. Both an Eisenmenger complex and a ventricular septal defect, anatomically, may correspond to what clinicians consider an Eisenmenger syndrome (ventricular septal defect with right-to-left shunt), on the one hand, or a ventricular septal defect with the usual left-to-right shunt, on the other.

**PATHOGENESIS OF THE COMPLEX** The overriding aorta may again be considered the primary anomaly and the ventricular septal defect as secondary. Flow from the right atrium into the right ventricle is normal. Flow from the right ventricle at birth, and in the young, is probably completely into the pulmonary artery, although there is probably some increase in pulmonary resistance. Increased pulmonary flow proceeds into the left atrium and ventricle. Flow from the left ventricle passes both into the aorta and into the right ventricle. Thus, the right ventricle presents both a pressure and a volume hypertrophy. The left atrium is enlarged because of increased flow, while the left ventricle may be normal in size or enlarged, because of increased flow and decreased pressure factors. With increasing age, the pulmonary resistance is known to increase and with it the pressure factor in the right ventricle, accompanied by decreased pulmonary flow.

**Common Truncus in an Overriding Position.** In this anomaly (Collett and Edwards, Humphreys et al., Kreutzer et al.), only one artery emerges from the heart, giving rise to the coronary, pulmonary, and systemic arteries. This anomaly must be differentiated from a truncus solitarius aorticus or pulmonalis, where a band (or minute blind artery representing the aorta or pulmonary artery) may be found. The common truncus straddles the ventricular septum over a defect of the latter. The right ventricle is hypertrophied, while the left ventricle may be hypertrophied, normal, or small. The architecture of the muscle bundles of the right ventricle, the defect of the ventricular septum, and the position of the coronary arteries are typical of overriding aorta. The

pulmonary trunk may come off beneath a partial septum, or the two pulmonary arteries of varying size may come directly from the aorta.

**PATHOGENESIS OF THE COMPLEX.** The common truncus may be considered as the primary abnormality, with the ventricular septal defect secondary (see Chap. 1). The right ventricle presents a pressure hypertrophy, since it is related to an increased pulmonary resistance. Blood from the left and right ventricles enters the common truncus and is distributed to the systemic and pulmonary circuits in different amounts, depending upon the size and position of the pulmonary arteries. Where there is a partial pulmonary trunk, there is increased flow (as in Eisenmenger's complex), and the left atrium is therefore hypertrophied and the left ventricle may be normal or large, depending upon the opposite effects of increased flow and decreased peripheral resistance (Eisenmenger type of common truncus). Where the pulmonary arteries come off directly from the truncus, more or less at right angles if they are of considerable size, the pulmonary flow may be normal but not increased. When the pulmonary arteries are small, then the flow is decreased. Under these circumstances, the left atrium is normal or small and the left ventricle is smaller than normal, resembling tetralogy of Fallot (Fallot type of common truncus).

**Partial Transposition with Pulmonary Hypoplasia (Fallot Type).** In this anomaly (Lev, 1953), a large aorta comes off almost completely from the right ventricle, in addition to the small pulmonary artery (Fig 6-8B). The defect of the ventricular septum is the same as in tetralogy of Fallot or larger. The right ventricle is markedly hypertrophied, while the left atrium and ventricle are small. The coronary ostia are still more rotated in a counterclockwise direction than in tetralogy of Fallot. The architecture of the muscle bundles is some-  
what atypical.

... which forms the crista, is still further deviated over the anterior wall of the right ventricle away from the anterior leaflet of the tricuspid. The crista so formed lies distal to, as well as above, the ventricular septal defect, which is bounded by the parietal band and an accessory small septal band lying posterior to the defect. An accessory parietal band

rides over the ventricular septum over a defect of the latter, emerging to a varying extent from both ventricles (Fig. 6-6A) The pulmonary artery is normal in size or enlarged. The defect is the same as that seen in tetralogy of Fallot. The right ventricle is again hypertrophied, but the left atrium and ventricle are larger than in Fallot. The aortic valve may be deformed, with

or without aortic insufficiency. The pulmonary valve ring may be sufficiently dilated to produce relative pulmonary insufficiency. The coronary ostia may be rotated as in Fallot. The architecture of the muscle bundles of the right ventricle may resemble that in Fallot, but frequently the parietal muscle bundle is enlarged rather than shortened.

**Etiology.** SA block is observed as a normal finding in individuals presenting an increased vagal tone. By itself, it is not considered abnormal. It may be produced in a susceptible individual by carotid sinus pressure. It is also observed in infectious states, during acute rheumatic carditis, in the presence of arteriosclerotic processes involving the SA node, and as a result of digitalis. Quinidine, procaine amide, and hyperkalemia may also produce this condition; however, these drugs tend to depress atrial contraction relatively early without concomitant effects on the ventricles; thus, they produce AV dissociation and ultimately sinus arrest with the maintenance of ventricular beats.

**Pathology.** No characteristic pathologic findings are observed in SA block. It may occur in patients with disease of the SA node due to

rheumatic carditis or degenerative conditions, it may follow occlusion of the right coronary artery, which supplies the SA node in 60 per cent of hearts. Occasionally, an arteriosclerotic process present in the region of the carotid sinus may tend to produce SA block by its increase of vagal tone.

**Symptoms.** No symptoms are usually observed with SA block. This arrhythmia may, however, produce symptoms under the following circumstances. Occasionally, the period of block may be prolonged to several seconds, resulting in syncope attacks. However, the periods of cardiac standstill are frequently shortened by the temporary assumption of the role of pacemaker by the AV node (*nodal escape*) or by a ventricular focus (*ventricular escape*). Such episodes may result in a sensation of palpitation or forceful beating of the

Fig. 11-16. A Partial AV block. Initial strip shows prolongation of the P-R interval, which measures 0.22 sec. Second strip, note the P-R interval prolongation with the tachycardia (ventricular rate, 150 per minute). Note that the P wave of the prolonged P-R interval immediately follows the preceding QRS complex, coming between the QRS complex and the T wave. This P wave controls the following QRS complex. B Partial AV block. Progressive increase in the prolongation of the P-R interval until a dropped ventricular beat is observed at  $P_x$  (Wenckebach phenomenon). C. Complete AV block. The atrial rate is 100, the ventricular rate is 37 per minute. Each pacemaker is beating independently of the other. D. Complete AV block with ventricular extrasystoles, some of which appear in groups of two in succession. Note the regular atrial rate of 88 per minute and a regular but slow ventricular rate (16 per minute) in most cycles, the two rhythms are entirely independent of each other.

should lead one to suspect the diagnosis (see Chap. 7).

In partial block (2:1), exercise or amyl nitrite may abruptly double the ventricular rate. When the apical rate is regular and ranges from 20 to 40 per minute and is relatively unaffected by exercise or atropine, complete AV block should be suspected. The 1st heart sound

relatively loud, when they are far apart, the 1st sound is faint (see also Chap. 8). The independent movements of the atria are usually visible upon a fluorescent screen.

The auscultatory phenomena in AV block should be differentiated from premature systoles, SA block, sinus arrhythmia, sinus bradycardia, and AV nodal rhythm. A 3:2 AV block may simulate a bigeminal rhythm. The diagnosis is clearly established by the electrocardiogram.

**ELECTROCARDIOGRAM.** Partial AV block is recognized easily by the electrocardiogram, which clearly shows regularly recurring, normally shaped P waves with prolonged P-R intervals (Fig. 11-16). The P-R interval is prolonged to over 0.21 sec in adults and over 0.18 sec in children. With a higher grade of partial block, dropped beats may be detected. However, prolongation of the P-R interval or nonconducted atrial impulses of other etiologies must be excluded. Thus, in atrial premature systoles and in the atrial beat occurring at the time of the nodal escape, prolonged P-R intervals, nonconducted atrial impulses, or both, may be observed. AV dissociation and interference dissociation may also be associated with P-R interval prolongation not due to partial AV block (see Chap. 11). In all these instances, the atrial impulse reaches the AV junctional tissue during its normal relative or absolute refractory phase. In AV block, on the other hand, the cause for the disturbance resides in a depression of the AV junctional tissue.

**Complete Atrioventricular Block.** In complete AV block, the atria beat regularly at a rate of 70 to 80 per minute in response to their pacemaker, the SA node, and the ventricles also beat regularly at a rate of 20 to 40 per minute in response to their center located in the lower portion of the AV node,

in the bundle of His, or in the upper portion of the interventricular septum. These two pacemakers function entirely independently of each other. The atrial rate is influenced by the vagus and by factors which influence sympathetic tone. With normal sinus rhythm, the ventricular rate is controlled entirely by the events occurring in the atria. In complete AV block, this situation no longer holds true since the ventricles presumably have no vagal innervation, therefore, they usually are not influenced by changes in vagal tone. The ventricular rate, however, can vary to some slight degree, being modified by factors that alter sympathetic tone, such as fever and the injection of epinephrine or other sympathomimetic drugs. If the idioventricular pacemaker is located in the lower portion of the AV node, terminal fibers of the vagus may partially control it. In such cases, a large dose of atropine may slightly increase the ventricular rate.

**ELECTROCARDIOGRAM.** The electrocardiographic diagnosis is easily made (Fig. 11-16). The ventricular complexes occur regularly and slowly. While the ventricular rate is usually slow, 30 to 40 per minute, it may be higher (60 per minute) in complete heart block due to digitalis, in the cycles immediately following emergence from Stokes-Adams seizures, it may be 100 per minute. The atrial complexes usually occur regularly at a normal rate. Occasionally, the atrial rate is quite rapid, 110 to 150 per minute; rarely it is slow, below 40 per minute. Occasionally, sequences are observed where two atrial beats are followed by one ventricular complex, thus resembling a 2:1 heart block. The Stokes-Adams syndrome is characterized by syncopal attacks, convulsions, or epileptiform seizures, and occurs when there is a period of anoxia lasting over 3 to 9 sec. These episodes are the chief hazard and usual cause of death in patients with complete AV heart block. The following are the underlying mechanisms recorded electrocardiographically during the seizures (Fig. 11-17): (1) a pre-fibrillatory type of ventricular tachycardia (ventricular flutter), (2) ventricular fibrillation, (3) standstill of the whole heart, (4) ventricular standstill with maintenance of atrial beating. These mechanisms may occur either singly or in various combinations.

**TREATMENT.** Complete Atrioventricular Heart Block. No specific therapy is indicated

## ATRIOVENTRICULAR BLOCK

**Complete Atrioventricular Block without Valvular Lesions.** Atrial sounds are present both in systole and diastole (Fig. 11-21B). In esophageal phonocardiograms and, occasionally, in precordial tracings, they present *three groups of low-pitched vibrations*: the first is caused by the atrial contraction, the second seems to be due to the resulting ventricular distention or a vibration of the AV valves, the third, to an elastic recoil of the ventricular walls. In precordial tracings, where the three groups are recorded, they occur 0.04, 0.12, and 0.27 sec after the respective P wave, and the duration of the atrial sound complex is from 0.34 to 0.36 sec. However, the first group of vibrations is seldom recorded. Then the atrial sound complex starts 0.08 to 0.12 sec after the P wave and lasts from 0.15 to 0.22 sec. The atrial sounds during systole consist of one or two groups of vibrations, and they can be larger than the diastolic. Their mechanism of production is still discussed. Some authors feel that these sounds are directly caused by atrial contraction which causes a vibration of the closed AV valves. Atrial murmurs can be seen in diastole in older patients 0.14 to 0.23 sec after the beginning of the P wave. These murmurs, occurring *after* atrial contraction, can be explained by sclerosis of the AV valves, which at first hinders their upward movement, causing a moderate regurgitation, and then delays their opening, thus slowing the normal

and murmurs may disappear if present, or, on the contrary, may appear during the attack.

**2 Posttachycardial syndrome.** Decreased loudness of the cardiac sounds, murmurs due to relative valvular insufficiency, and triple rhythm are frequent. Following ventricular tachycardia, one can see a marked decrease in amplitude of the 1st sound, a systolic murmur in decrescendo, and a triple rhythm (summation type). The last two had disappeared during the attack but were previously present.

## NODAL RHYTHM

The changed time relationships between atrial and ventricular systoles cause marked changes of the phonocardiogram. If present, an atrial 4th sound disappears. The vibrations of the 1st sound, owing to closure of the AV valves, have an amplitude which varies in proportion to the P-R interval. This is because of different tension of these valves at the beginning of systole. In nodal rhythm, the 1st sounds have constant loudness, while in cases of wandering pacemaker, there are continuous changes. A short systolic sound due to atrial contraction may appear.

## SINOATRIAL BLOCK

There are only two published phonocardiograms in cases with bigeminal SA block. The cardiac sounds either remain unchanged, or they alternate in amplitude, number of vibrations, and duration (Fig. 11-21A).

Fig 11-20. Ventricular tachycardia. Phonocardiogram (stethoscopic) 3M. (0.02 in and 0.10 in). A and B are consecutive sections of the same tracing.

posite directions, giving rise to the isoelectric or transitional P wave. Such beats are said to be *fusion beats*.

## ATRIOVENTRICULAR BLOCK

**Partial Atrioventricular Block.** Atrioventricular (AV) block may be divided into two types: partial, or incomplete, and complete. AV block may be *temporary*, *intermittent*, or *permanent*, and one type may develop into the other. The first stage of AV heart block is said to occur when the AV conduction time (P-R interval) exceeds 0.20 sec. As the degree of block increases, the AV conduction time becomes longer and longer until dropped beats occur, i.e., the ventricles fail to respond to some atrial beats. In a still higher grade of block, there may be observed 2:1, 3:1, or an even higher degree of partial AV block. As the block further increases, a stage is reached in which the ventricles fail to respond to *any* atrial impulse, with the result that ventricles and atria beat entirely independently of each other. When this stage is reached, the degree of AV block is said to be *complete*.

**Sudden death** may occur during the transition from partial to complete block because of ventricular standstill or ventricular fibrillation.

Clinical heart block has been observed as the result of the following: (1) infections, (2) certain drugs, especially digitalis and, to a lesser degree, quinidine and Pronestyl; (3) congenital cardiac anomalies, (4) vagal stimulation; (5) degenerative conditions; and (6) hypoxia. A discussion of these conditions follows.

**PATHOLOGY.** Coronary artery disease, acute or chronic, is the most common cause of AV block in the older age group. The right coronary artery supplies the AV node in 92 per cent of hearts, the left coronary in 8 per cent. Gummata occurring in the AV node or bundle of His are rare (see also Chap. 5).

**SYMPTOMS AND SIGNS** In partial AV block, no symptoms due to the block itself may be observed, even with a slow ventricular rate. The symptoms are those of the underlying disease. Some patients with complete AV block present no symptoms, usually, however, they complain of fatigue on exertion, occasional precordial pain, and consciousness of a vigorous, slow, forceful heart action. These patients usually cannot engage in strenuous physical exer-

tion but generally do fairly well on a reduced physical regimen.

As a result of the slow rate, alterations in the cardiovascular dynamics appear. The cardiac output per beat is increased, but the cardiac output per minute, compared to the normal, may be decreased in some patients. In complete AV block, because of the fixed cardiac rate, the mechanism for increasing cardiac output in response to exertion and excitement is seriously impaired. Exertion may lead to the production of an extrasystolic arrhythmia and, if continued, may precipitate a Stokes-Adams attack. The systolic blood pressure is elevated, rising to about 170 to 200 mm; the diastolic pressure is usually low, 80 to 100 mm. It is distinguished from true hypertension by the relatively low diastolic pressure resulting from the longer emptying time available to the large arteries between heart beats. The systolic pressure rise is evidence of the enhanced vigor of the slow beats resulting from the greater filling time allowed the heart. The heart, particularly the left ventricle, is enlarged.

The important symptoms to be considered in the higher grades of partial and complete AV heart block are the development of *giddiness*, *fainting*, and *temporary loss of consciousness*, with or without convulsive seizures (*Stokes-Adams syndrome*). These manifestations of cerebral hypoxia occur during the transition from partial to complete AV heart block, as well as during the course of complete cessation of cerebral flow for 3 to 9 sec or longer.

**DIAGNOSIS.** The possibility of AV block should be suspected in the presence of any of the conditions mentioned above, especially rheumatic fever, coronary diseases, digitalis, toxic factors, etc. Suggestive evidence consists in a *diminished intensity of the 1st heart sound*, which may be marked. In the presence of dropped beats, the auscultatory phenomena closely resemble and should be differentiated from extrasystoles with a compensatory pause. When there is a delay in AV conduction (prolonged P-R interval) with a regular rhythm ranging from 50 to 80 per minute, the diagnosis is practically impossible by auscultation alone. With rates below 50 or 40 per minute, the possibility of partial or complete heart block should be considered. The presence of a jugular pulse more rapid than that of the apex

sound, on account of the variable duration of diastole.

**Cases with Mitral Lesions.** Frequently the sclerosis of the mitral cusps increases the loudness of the 1st sound and causes its splitting. The Q-1st sound interval, which is particularly prolonged in mitral stenosis, becomes even longer if there is atrial fibrillation. This interval is inversely proportional to the duration of the preceding cardiac cycle: shorter diastole = longer interval (Luisada, Cossio). The *opening snap* of the mitral valve has duration and intensity which vary for every cycle (Rappaport and Sprague; Wells). This snap is more distant from the 2d sound when left atrial pressure is lower; therefore, it is more distant after a long diastole. Murmurs of mitral origin are known to disappear when atrial fibrillation starts. This is particularly true for the pre-systolic murmur, while the systolic and the mid-diastolic murmurs may disappear for a time and reappear later. On the other hand, the mid-diastolic murmurs of mitral stenosis may be louder than in cases with sinus rhythm. This may be explained by the fact that left atrial pressure is higher. A *ventricular type* of triple rhythm is frequent in mitral insufficiency, occasionally present in moderate mitral stenosis, and absent in severe mitral stenosis. It may simulate an opening snap

## EXTRASYSTOLES

Extrasystoles (Fig. 11-19D) are characterized by the premature appearance, and possibly by the occasional absence, of cardiac sounds and murmurs. Other possible signs are due to the extrasystole itself. Others may affect the preceding cycle (preextrasystolic signs) and some of the following beats

The 1st sound is usually accentuated and delayed, the Q-1st sound interval being from 0.08 to 0.10 sec and even 0.12 sec. The main vibrations may be from two to four times higher than those of the normal contractions. Sometimes the 1st sound is decreased and may be completely absent, it may be either shortened or prolonged, it may be split, but this is seen only in ventricular extrasystoles, on account of marked asynchronism of closure of the mitral and tricuspid valves.

Ventricular systole is usually short. The 2d sound is usually small and may become so faint as to disappear. This is more frequent in

cases of early extrasystoles, especially if they are interpolated. Absence of both sounds is extremely rare; in such cases, the extrasystole is clinically mute. Because of asynchronism of the closure of the semilunar valves, splitting of the 2d sound may occur in ventricular extrasystoles. On the other hand, previous splitting of the 2d sound may disappear during the extrasystole.

**Triple Rhythms.** The atrial type disappears in ventricular extrasystoles because of the absence of atrial contractions. On the other hand, following an extrasystole, a ventricular type of triple rhythm may occur, or it may disappear if it was regularly present in the normal cycles. A summation type of triple rhythm may be seen in atrial or sinus premature contractions. It is due to coincidence of the rapid filling of the preceding beat with the following atrial contraction. Extrasystoles may either increase or decrease the loudness of murmurs. The latter may even disappear during an extrasystole because of inadequate filling of the ventricles.

The extrasystoles may modify some of the graphic characteristics of the preceding cardiac cycle. For instance, when they occur very early, the 1st sound may coincide with a 3d sound, and even with the 2d sound of the previous cycle. This may cause increased loudness of that 2d sound, a summation type of triple rhythm, or an accentuation of the early-diastolic murmur of mitral stenosis. On the other hand, this murmur may disappear if several premature contractions occur in a row.

The 1st sound is frequently increased in the beat immediately following the extrasystole and, at times, in the second or third subsequent beat. Occasionally, *alternans* develops.

## VENTRICULAR TACHYCARDIA

The phonocardiographic signs of the ventricular tachycardias are similar to those of the supraventricular forms.

1. **The attack.** During the attack, ventricles and atria beat independently and, now and then, contract at the same time. The 1st sound presents characteristic changes consisting of occasional sudden increase of loudness (Fig 11-20). The 1st sound may be prolonged or split, either constantly or intermittently, and is usually delayed. The 2d sound occurs early (short systole). Diastole is even shorter. As in supraventricular tachycardia, triple rhythms

1 to 2 hr, depending on desired results, or may be given as a 1:1,000 solution in oil (10 ml intramuscularly).

3 *Isuprel* may be given sublingually in doses of 10 to 20 mg every 2 hr or as required, subcutaneously 0.2 mg every 1 hr or as indicated, or intravenously as a continuous infusion of 1 mg *Isuprel* dissolved in 200 ml of 5 per cent glucose in distilled water, or 4  $\mu$ g per ml, at a rate of 9 to 20 drops per minute.

4 Molar sodium lactate is effective when given promptly, preferably within 1 to 2 min after the onset of the attack. Initially, it should be given intravenously by syringe in doses of 20 to 40 ml in 1 to 2 min during the attack; then, the solution should be administered as an intravenous infusion at the rate of 60 to 150 drops per minute, the exact rate and amount depending on the effects observed. As the ventricular rate increases, the infusion should be slowed; when it becomes apparent that the pacemaker is spontaneously maintaining a satisfactory rate and the episodes of cardiac arrest have been eliminated, the infusion should be stopped.

5 An artificial pacemaker will restore car-

diac beating during cardiac arrest. Its use may be lifesaving (see Chap. 12).

6. Because these seizures are so often repeated, thoracotomy accompanied by cardiac massage should be used only when all other methods fail.

7. *Barium chloride* increases the rhythmicity of the cardiac pacemaker but is not frequently used because of its toxic effects.

8. Quinidine and procaine amide have been used in the past when the Stokes-Adams seizures were associated with ventricular extrasystoles, ventricular tachycardia, or ventricular flutter. The administration of these drugs is considered to be contraindicated because they depress cardiac pacemakers.

9 Digitalis in the presence of congestive failure should be used with caution because of its effect in increasing cardiac irritability. AV block, if complete, is not a contraindication to the use of digitalis. Incomplete AV block, on the other hand, might be transformed into complete block by digitalis.

10. Defibrillation may be accomplished by application of the defibrillator (see Chap. 12) to the closed chest or after thoracotomy to the exposed heart.

and murmurs may disappear if present, or, on the contrary, may appear during the attack.

2 *Posttachycardial syndrome.* Decreased loudness of the cardiac sounds, murmurs due to relative valvular insufficiency, and triple rhythm are frequent. Following ventricular tachycardia, one can see a marked decrease in amplitude of the 1st sound, a systolic murmur in decrescendo, and a triple rhythm (summation type). The last two had disappeared during the attack but were previously present.

### NODAL RHYTHM

The changed time relationships between atrial and ventricular systoles cause marked changes of the phonocardiogram. If present, an atrial 4th sound disappears. The vibrations of the 1st sound, owing to closure of the AV valves, have an amplitude which varies in proportion to the P-R interval. This is because of different tension of these valves at the beginning of systole. In nodal rhythm, the 1st sounds have constant loudness, while in cases of wandering pacemaker, there are continuous changes. A short systolic sound due to atrial contraction may appear.

### SINOATRIAL BLOCK

There are only two published phonocardiograms in cases with bigeminal SA block. The cardiac sounds either remain unchanged, or they alternate in amplitude, number of vibrations, and duration (Fig. 11-21A).

### ATRIOVENTRICULAR BLOCK

*Complete Atrioventricular Block without Valvular Lesions.* Atrial sounds are present both in systole and diastole (Fig. 11-21B). In esophageal phonocardiograms and, occasionally, in precordial tracings, they present three groups of low-pitched vibrations: the first is caused by the atrial contraction, the second seems to be due to the resulting ventricular distention or a vibration of the AV valves, the third, to an elastic recoil of the ventricular walls. In precordial tracings, where the three groups are recorded, they occur 0.04, 0.12, and 0.27 sec after the respective P wave, and the duration of the atrial sound complex is from 0.34 to 0.36 sec. However, the first group of vibrations is seldom recorded. Then the atrial sound complex starts 0.06 to 0.12 sec after the P wave and lasts from 0.15 to 0.22 sec. The atrial sounds during systole consist of one or two groups of vibrations, and they can be larger than the diastolic. Their mechanism of production is still discussed. Some authors feel that these sounds are directly caused by atrial contraction which causes a vibration of the closed AV valves. Atrial murmurs can be seen in diastole in older patients 0.14 to 0.23 sec after the beginning of the P wave. These murmurs, occurring after atrial contraction, can be explained by sclerosis of the AV valves, which at first hinders their upward movement, causing a moderate regurgitation, and then delays their opening, thus slowing the normal

for the *asymptomatic* type of AV block; these patients do fairly well with a slow rate, which may range from 30 to 40 per minute. In the *symptomatic* type of AV block, in which the patient experiences frequent fainting episodes, administration of one or more of the following drugs is indicated: (1) sympathomimetic drugs (ephedrine, Isuprel), (2) oral molar sodium lactate.

**Stokes-Adams Seizures.** Prophylaxis consists of avoiding those factors which tend to precipitate attacks; ■ g., strenuous exertion and emotional upsets. Between attacks, measures

as described for AV block may be used. The active measures during an attack consist of the following:

1. Direct vigorous thumping on the precordium.

2. *Epinephrine* by intracardiac injection (0.25 to 1 ml of a 1:1,000 solution). This may also be given by slow-drip intravenously, but not more than 0.25 mg should be given by this route, and the drug must be administered at a very slow rate. To prevent repeated attacks, epinephrine may be given in doses of 0.2 to 0.3 ml subcutaneously every

Fig. 11-17. Cardiac mechanisms during a Stokes-Adams attack. Strips A, B, C, D, and E are taken from the same patient, who had a complete AV block. A. Paroxysm of ventricular flutter with a ventricular rate which averages about 200 per minute. Note the markedly aberrant type of ventricular complexes. The end of the strip shows the resumption of the complete AV heart block. B. Ventricular flutter with a rate of about 200 per minute, terminating in ventricular standstill. The atrial rate is maintained at 100 per minute. C. Emergence from an attack of ventricular standstill, with the appearance of occasional idioventricular beats. D, and E. Ventricular fibrillation. Note the markedly aberrant type of ventricular response. The patient recovered from this paroxysm but succumbed during a subsequent attack.

ventricular filling. In other words, slight insufficiency and stenosis would take place in turn, both of them functional and of short duration.

**FIRST SOUND.** Splitting of the 1st sound has been described. It is due to two separate groups of ventricular vibrations. Splitting may be simulated by presystolic or systolic occurrence of an atrial sound. Changes in amplitude of the 1st sound are also typical of complete AV block. In long tracings, one can see marked

changes in amplitude from one beat to the next. The 1st sound may disappear almost completely, or it may increase in amplitude up to five or six times (*cannon sound*). The frequency, duration, and number of vibrations of the 1st sound usually follow the changes in amplitude. Thus, an increased 1st sound has a higher pitch and more vibrations. A definite relationship has been found between the amplitude of the 1st sound and the duration of

Fig. 11-21. A. Sinus bigeminy. B. Complete AV block. C. Incomplete AV block with Wenckebach periods. All phonocardiograms (stethoscopic) 5L6

arteries nearer the heart but not in those more distant. When failure is severe, a high pulse wave may be followed by gradually smaller ones (*Galienus's pulse*).

As long as the conditions of the myocardium are good, the stroke volume is directly proportional to the length of the preceding diastole and inversely proportional to the stroke volume of the preceding cycle. (This, however, is approximate and not exact.) If there is cardiac failure, no rule can be established. The speed of the small pulse waves is always greater than that of the large waves.

**Electrocardiogram.** This tracing has been studied by Lewis and Terry, Boone et al., and Engstroem et al. The atrial tracing shows the absence of atrial waves. The waves of the ventricular and arterial tracings (both the aortic and the pulmonic) have a variable amplitude, which is roughly proportional to the length of the previous diastole.

## PREMATURE BEATS

**Jugular Tracing.** Atrial premature beats have A, C, and V waves which are similar to those of a normal tracing. Nodal and ventricular premature beats, on the other hand, frequently have a high A wave, because of simultaneous atrial and ventricular contraction which is accompanied by a venous regurgitant wave.

A left ventricular premature beat may show a delay of V over the 2d aortic sound (early contraction of the left ventricle, later contraction of the right, with late opening of the tricuspid valve).

**Arterial Tracing, Hemodynamics.** The pulse wave of the premature beat may be as high as a normal wave and occasionally higher. It is usually smaller and may be absent on account of small ejection or even lack of ejection. Records taken over different arteries show that the pulse wave of the premature beat may be present in the arteries near the heart (carotid) and absent in those distant (tibial arteries). A drop in pressure occurs during the compensatory pause. The following wave is higher than normal, and is followed by a smaller wave; this may start a *pulsus alternans*.

The pulse of the premature contraction has a low systolic and a high diastolic pressure, while the following pulse is much larger, having a high systolic and a low diastolic pressure.

Fig. 11-18. Tracings revealing a greater number of atrial waves than ventricular waves. A. Multiple waves of atrial origin in the jugular tracing of a patient with atrial flutter. B. Multiple waves in the left atrial border electrokymogram of a patient with atrial flutter. C. Multiple waves in the right atrial border electrokymogram in a patient with complete AV block. Above, phonocardiogram; below, EKY.

From two to three pulse waves are necessary for reaching again a normal and stable level of blood pressure. On the other hand, the first normal contraction following an interpolated premature beat frequently yields a smaller pulse wave in the peripheral arteries (a short diastole precedes such an extrasystole).

The pulse wave of a right ventricular premature beat may be delayed over the beginning of the corresponding 1st apical sound

## SUPRAVENTRICULAR TACHYCARDIA

**Jugular Tracing.** There is only one high wave, owing to fusion of the various waves. If the atrial and ventricular contractions occur exactly at the same time, this venous wave becomes high, because if the right atrium cannot push the blood forward against the closed tricuspid valve, it will push it backwards, into the large veins.

**Arterial Pulse.** The pulse becomes small during the attack. The dicrotic wave, however, may be relatively higher, and its fusion with the following pulse wave may simulate an anacrotic pulse. The speed of the pulse wave is often reduced.

## VENTRICULAR TACHYCARDIA

**Jugular Tracing.** High atrial waves are recorded, at a rate which is slower than that of the arterial pulse (unless there is atrial fibrillation). The waves may be slightly irregular.

**Arterial Tracings.** The pulse waves are small and may show a variable height, then, a higher wave caused by the casual precedence of an atrial contraction over a ventricular. There may be *pulsus alternans*.

## ATRIAL FLUTTER

**Low-frequency Tracing of the Precordium.** Atrial waves may be recorded in the intervals between the ventricular waves of this tracing.

**Jugular Tracing.** Regular atrial waves were recorded by several workers. More recently,

Contro has recorded high atrial waves in five cases of flutter by means of a linear microphone and an amplifier. These waves gave evidence of the coordinated contractions of the atria.

**Electrokymogram.** If the slit of the pickup is placed across the border of either atrium, good evidence of atrial contractions can be secured (Fig. 11-18A, B). The atrial waves are usually of large amplitude, and their detection is important in cases where the electrocardiographic tracing had led to admission of "pure fibrillation."

## ATRIAL FIBRILLATION

**Jugular Tracing.** The C and V waves follow each other with complete irregularity. There are no A waves, because of the fibrillation.

**Low-frequency Tracing of the Precordium.** The waves caused by ventricular contraction are of various height and configuration. When diastole is short, the subsequent isometric tension period becomes longer. The height of the waves varies somewhat but is not exactly proportional to the length of the preceding diastole.

**Arterial Tracings, Hemodynamics.** The pulse waves are typically irregular, having various heights, lengths, and configurations. Patients in congestive failure often have a pulse deficit because some of the ventricular contractions have such a small ejection that they are not followed by a pulse wave. However, when ejection is small, waves may be present in the

## 11-62 RATE, RHYTHM, AND CONDUCTION DISTURBANCES

**Atrioventricular Block with Mitral Lesions.** The valvular lesion frequently causes the 1st sound to be less decreased than when the mitral valve is normal. The systolic murmur of mitral insufficiency may decrease or disappear if there is a short P-R interval; this is because atrial contraction somewhat resists the regurgitant jet (only for a short time) and gives a greater tension to the mitral ring. Every atrial contraction may be followed by a murmur, during the long diastole, three or four murmurs may be seen with regular intervals and progressively decreasing amplitude. This is because the increased diastolic filling of the ventricles gradually hinders further filling due to atrial propulsion.

**Incomplete Atrioventricular Blocks.** In a 2:1 block, one may see two atrial sounds, one in protodiastole and one in presystole (Fig. 11-21C). The former may coincide with and accentuate the 2d sound, it may fall during rapid filling, thus causing a summation type of triple rhythm, or it may give a delayed diastolic sound. In cases without valvular lesions, every P wave may be followed by an atrial murmur, as in complete AV block, in cases with mitral stenosis, the P wave may be followed by a loud diastolic murmur. In both cases, a short systolic murmur is also usually present. In *Wenckebach periods*, the diastolic atrial sounds

parallel the cyclic variations of the P-R interval. This holds true both for the presystolic murmur of mitral stenosis and for the atrial sounds and murmurs in cases without valvular lesions (Fig. 11-22A). The magnitude of the 1st sound varies according to the duration of the P-R interval; it may become progressively decreased, accentuated, or split.

**FIRST DEGREE OF ATRIOVENTRICULAR BLOCK** Phonocardiographic evidence of atrial activity (sounds, murmurs) occurs earlier in regard to the 1st sound. If tachycardia is present, such murmurs may even become mid- or early diastolic. Thus, they may coincide with the opening snap of the mitral valve, with a 3d sound, or with the early diastolic murmur of mitral stenosis. Unusual auscultatory rhythms may arise in this way.

**Wolf-Parkinson-White Syndrome.** Only a few phonocardiograms have been published to date. The interval Q-1st sound is normal; the 1st sound has a normal magnitude (Fig. 11-22B). The 2d sound is neither split nor delayed. A 3d sound may be recorded. These data may be interpreted as indicating that (1) there is no bundle branch block (in the normal sense), (2) the P-R interval is only apparently shortened, (3) AV valves closure occurs at a normal distance from the P wave, in spite of the so-called *delta wave*.

ALDO CALO

## SUPRAVENTRICULAR TACHYCARDIA

The findings during the attack should be considered separately from those obtained after reestablishment of *sinus* rhythm. The latter may be considered as the result of a post-tachycardial phonocardiographic syndrome.

**The Attack.** Increased loudness of the 1st sound = frequent. Even though loudness may progressively increase during the first few beats of the attack, once the maximum loudness has been reached, the 1st sounds continue with the same magnitude, small variations in amplitude may be due to respiratory variations. The increased loudness of the 1st sound may be caused either by summation of the 1st with the 4th (atrial) sound, or by changes in the mechanism of closure of the AV valves.

In low nodal tachycardia with retrograde conduction, the atrial sound may show up in the tracing soon after the 1st sound, causing splitting of the 1st sound (Fig. 11-19A). Actually, it is not a real splitting but the addition of a new sound (atrial) in early systole. **Alternans** = exceptional. If present in the above cases, alternans affects only the ventricular component, i.e., the 1st sound, while the atrial sound is unaffected. The 2d sound may be accentuated, split (either occasionally or continuously), or small, to the point of disappearance. Both systole and diastole are markedly shortened, the latter more than the former. As diastole becomes progressively shorter and the atrial contraction is closer to the rapid filling of the preceding cycle, a summation type

of triple rhythm (summation gallop) occurs. Several murmurs may appear during attacks of tachycardia of long duration. They have been explained as the result of increased speed of flow, changes of the normal sequence of atrial and ventricular contractions, or relative insufficiency of the mitral valve. The latter might be due to ventricular dilatation as a result of strain. On the contrary, preexisting murmurs caused by valvular lesions or shunts may disappear during an attack.

**Posttachycardial Syndrome.** The phonocardiographic signs of this syndrome may consist of changes of the sound and murmurs present before the attack; disappearance of signs brought about by the attack itself; return of signs obscured by the attack; and, finally, appearance of new phonocardiographic data. After *sinus* rhythm is reestablished, the following may be found: 1st and 2d sounds—true or false splitting, alternans may either decrease or disappear. Systole and diastole regain their normal values. A summation type of triple rhythm, originated by the attack, may disappear. On the other hand, a new triple rhythm may appear after the attack because of myocardial insufficiency. The same may be said for murmurs which may disappear, reappear, or start after the attack. These murmurs are usually of mitral origin and are functional.

## ATRIAL FLUTTER

In most cases, the atrial sounds, which on occasion may become abnormally large and even clinically audible, may have no time re-

### BUNDLE BRANCH BLOCK

#### MODERN CONCEPTS OF VENTRICULAR ACTIVATION

The bundle branch block concept rests upon the knowledge of the process of ventricular activation which takes place in the conducting tissues of the heart, originating in the SA node, spreading through the atria to the AV node, the bundle of His and its two stems, and finally reaching the myocardial fibers through the sub-endocardial Purkinje network.

When one of the branches of the bundle of His fails to conduct the stimulus, the order of ventricular activation is modified and certain electrocardiographic changes appear which are characteristic of the various types of bundle branch block. These abnormalities depend not only upon whether the right or the left bundle branch is involved but also upon the severity of the lesion and the degree of conduction disturbance.

According to studies of Sodhi Pallares et al (1958), the first part of the ventricular myocardium to be activated is the interventricular septum, which is no longer considered as a syncytial mass, but rather as two separate portions, separated by a "barrier," in which the muscle fibers are diversely oriented with multiple synaptic connections, in addition, these septal fibers have different polarities.

The greater part of the septum belongs to the left ventricular myocardium, so that it forms the

entire posterobasal aspect of the septum, which is completely devoid of right ventricular fibers. Thus, the left ventricle encroaches upon certain areas of the endocardial surface of the right ventricle, and an electrode placed at this point may actually record left ventricular potentials. The right ventricular component of the septum represents only a minor fraction of its entire mass.

The interventricular septum is activated from both the right and left endocardial surfaces. The left bundle branch is responsible for the activation of the entire left septal surface, as well as for most of the septum proper, whereas the right branch supplies a very small portion of this structure.

Since the left ventricular septal mass is greater than that pertaining to the right ventricle, it is obvious that the resultant vector is directed from left to right.

The beginning of ventricular activation takes place at the middle third of the septal surface, and spreads from left to right, anteriorly and upwards. The last points to be activated are the anterobasal portions of the right septal surface.

The right surface of the septum is normally activated 0.01 sec after the left, whereas the last portions are activated 0.03 sec later (Fig. 11-23A).

The initial septal vector is responsible for the small Q wave which is usually recorded in the leads overlying the left ventricle, and which is due to activation of the left septal mass. This process

(earlier contraction of the right ventricle, subsequent contraction of the left, responsible for the pulse).

The *stroke volume* varies greatly, being inversely proportional to the length of the preceding diastole. Therefore, the earlier the contraction, the smaller the stroke volume. The compensatory pause is followed by a contraction which has a proportionally larger stroke volume. This, however, is not true if the myocardium is weak.

The speed of the pulse wave is directly proportional to the level of diastolic pressure; therefore, the weak pulse of the premature contraction has a greater velocity than the others.

**Blood Pressure Tracings.** Different levels of blood pressure can be obtained if the premature beats occur periodically. (1) those corresponding to the systolic and diastolic pressure of the normal pulse waves, (2) those corresponding to the pulse waves of the premature beats (low systolic, high diastolic); and (3) those corresponding to the pulse waves immediately subsequent to the premature beats (high systolic, low diastolic).

**Low-frequency Tracing of the Precordium.** The premature contraction may give waves of normal configuration. The isometric tension period is often prolonged. This may cause bizarre or large waves.

**Electrokymogram.** Premature contractions are easily studied by means of border tracings of the left ventricle, the pulmonary artery, or the aortic arch. If simultaneous tracings of the left ventricle and one of the arteries (aorta or pulmonary artery) are taken, conclusions may be drawn about the site of origin of a ventricular premature beat. The aspect of the tracing depends upon the time of the cardiac cycle at which the premature contraction occurs and the phase of the ventricular filling.

If the contraction starts early in diastole, its amplitude is small, isometric contraction is prolonged, and the curve assumes a more peaked aspect. The isometric tension period may last more than 0.06 sec on account of both the high level of arterial pressure and the small amount of ventricular blood. If the contraction takes place immediately after the T wave, no ejection may occur. During the com-

pensatory pause, an abnormally large filling of the ventricles takes place. This, plus the lower level of arterial pressure, causes a shortening of the isometric tension period of the following contraction.

## ATRIOVENTRICULAR BLOCK

**Jugular Tracing.** The A waves are normal in shape and follow each other, usually, at a normal rate; the C and V waves occur at regular, but much longer, intervals. Therefore, more than one A wave is found between a V wave and the next C wave. Occasional coincidence of an A wave with a C or V wave may occur, with a resulting higher wave.

**Arterial Tracing.** A high and slow pulse is recorded. An anacrotic depression is frequently present in the ascending branch of the pulse curve. Multiple undulations follow the diastolic wave.

In *occasional block*, the tracings reveal the occasional absence of a pulse wave (*intermittence*). In *periodic block*, the series of pulse waves shows a periodic increase in the pause separating two pulses, then a longer pause with a deeper pressure drop. *Interference dissociation* may cause a bigeminal rhythm, the second wave being paradoxically *higher* than the first (Fischer).

**Low-frequency Tracing of the Precordium.** High atrial waves are present between the waves caused by the ventricular contractions.

**Electrokymography.** The electrokymogram of AV block has been studied by the author, Engstroem et al., and Pannier et al.

**ATRIAL TRACINGS** If atrial contraction falls during ventricular systole, the atria decrease in volume as in normal subjects; apparently the blood is pushed backwards into the veins. If the atrial contraction falls during ventricular diastole, the pattern consists of an oblique, descending line during atrial contraction, and a less steep rise subsequent to it. The depth of the contraction varies, it is usually larger when the atrial contraction falls during a ventricular contraction because of additional ventricular pull (Fig. 11-18C).

**LEFT VENTRICULAR TRACING.** The tracing of the left ventricle may not show any effect of the atrial contractions. If it does, the latter are revealed by small positive waves.

is initiated at the left ventricular endocardium and spreads toward the septal fibers at the base of the anterior papillary muscle of the right side of the septum, which at this level is probably still formed by the left ventricle.

The late activation of the basal portions of the septum is due to the scarcity of the Purkinje network at this level. It probably contributes to a great extent to the third cardiac vector (so-called "final vector"), although this is variable from one individual to the other.

Following the initial septal activation, the depolarization process spreads to the free walls of both ventricles perpendicularly, from the endocardium to the epicardium. Studies of Prinzmetal et al (1953) confirmed by Sodi Pallares (1956) have demonstrated that approximately two-thirds of the subendocardial aspects of the free walls of both ventricles are simultaneously and almost instantaneously activated, having practically no electrocardiographic representation. The potentials obtained in this area are similar to those recorded in the ventricular cavities, this portion of the myocardium was designated as the *electrical endocardium*, since from the standpoint of cardiac activation, it merely represents an extension of the cavity. The spread of excitation through the electrical endocardium is extremely rapid, having an approximate speed of 2,000 to 4,000 mm/sec. This

is explained by the deep penetration of the Purkinje fibers into this part of the cardiac muscle.

The activation of the free wall of the ventricles is responsible for the second cardiac vector, which is primarily due to the predominance of electrical forces of the left ventricle, ten times greater than those of the right ventricle, the latter being insignificant from the standpoint of the vectorial analysis of the electrocardiogram in normal individuals (Fig. 11-23B).

This second cardiac vector is generally of great magnitude, is directed toward the left, posteriorly and downwards, and is seldom influenced by the right ventricle (this may occur in cases of extreme right ventricular hypertrophy). The predominance of the electrical forces of the left ventricle in cardiac activation explains the counterclockwise rotation of the normal vectorcardiogram in the horizontal plane.

The process of activation varies according to the degree of block. Thus, it becomes important to distinguish between complete and *incomplete bundle branch blocks*. This concept was established on the basis of experimental studies (Rodriguez and Sodi Pallares), by comparing the electrocardiograms obtained in dogs with various degrees of bundle branch block, and those of a human being's tracing with

Fig. 11-23. A Septal activation. B The three main cardiac vectors. C and D. Schematic representation of the four vectors resulting from ventricular activation in right bundle branch block, and the corresponding deflections in lead  $V_1$  and in the right ventricular cavity.

lationship with the main heart sounds. In other cases, changes of cardiac sounds, murmurs, and intervals may be produced by a profound alteration in the hemodynamics caused by the disturbance of rhythm (Fig. 11-19B). The atrial sounds recorded from the esophagus start 0.04 sec after the P waves, most likely they are produced within the atria. The atrial sounds recorded over the precordium are far more delayed because they start from 0.14 to 0.24 sec after the P waves and 0.10 sec after the A waves of the jugular tracing. This indicates that the precordial atrial sounds are originating either in the ventricular walls or in the AV valves. In general, each atrial sound consists of a single group of 1 to 4 low-pitched vibrations, lasting from 0.03 to 0.08 sec. Exceptionally they last 0.16 sec and present two separate components, one with a single high vibration, and the other with several lower vibrations (see Atrioventricular Block, further on in this chapter, for explanation). The amplitude of atrial vibrations is usually small, but in certain cases they may be one-half of either heart sound. Sounds produced during systole are often higher than those originated in diastole. In irregular flutter, the amplitude of these sounds is variable and some of them may be absent in spite of ECG evidence of atrial contractions. The modifications of cardiac sounds, murmurs, and intervals produced by *regular flutter* are constant, while variable and inconstant findings are found in *irregular flutter*, where marked changes of dynamics occur.

The changes of the 1st sound are closely related to the duration of the P-R interval or P-1st sound interval, which are equivalent. For values between 0.08 and 0.12 sec, the 1st sound = increased in loudness (an occasional increase is typical of irregular flutter). For higher or lower values, the 1st sound either may be decreased or may present a systolic or presystolic addition of an atrial sound (*pseudo splitting*). The 1st sound may be delayed over the beginning of the QRS complex, may be of small amplitude, and may be alternating. The 2d sound may be increased, decreased, or split. In irregular flutter an occasional accentuation may be due to addition of an atrial sound to the 2d sound. At times, the 2d sound may disappear because of weak ventricular systole, as in some types of extrasystoles or cases of atrial

fibrillation. A summation type of triple rhythm can take place whenever an atrial contraction coincides with the phase of rapid ventricular filling. In regular flutter, this may happen after every ventricular systole; in irregular flutter, it may happen occasionally.

It is a common notion that the *presystolic murmur* of mitral stenosis disappears whenever the left atrial contraction fails to occur. The fluttering left atrium may display such a powerful systole as to accelerate the flow across the mitral valve. This results in a *loud murmur for every atrial contraction* which takes place in diastole (in systole, it is obvious that the atrium cannot open the mitral valve). The *systolic murmur* of mitral insufficiency may disappear or change in character during atrial flutter, and it may reappear or increase after reestablishment of the sinus rhythm.

## ATRIAL FIBRILLATION

Atrial fibrillation is characterized by a complete arrhythmia of cardiac sounds and murmurs with irregular variations for every cycle. An exception is represented by rare cases with idioventricular rhythm.

*Cases without Valvular Lesions.* The 1st sound is usually *delayed* over the R wave but this delay is *small*. Its amplitude and duration are variable, so that the 1st sound may become quite small or very large. Apparent splitting is frequent; this may be due to a separation of the valvular components or, in the case of a very short diastole, to the occurrence of a ventricular type of triple rhythm (gallop) immediately followed by the 1st sound (Fig. 11-19C). The 2d sound usually presents continuous changes of amplitude and duration which are independent from those of the 1st sound. There also may be an occasional splitting due to asynchronism of the semilunar valves.

In some cases, the apical phonocardiogram may show a *short systolic murmur*, which, in the absence of any valvular lesion, is thought to be due to functional mitral insufficiency or to the formation of eddies. Even though no atrial or summation type of triple rhythm may occur on account of the lack of atrial contractions, various types of triple rhythm may occur. These are due to the addition of a ventricular sound which may fall in early diastole, mid-diastole, or just prior to the following 1st

similar configurations. It was observed that the complete section of one of the branches of the bundle of His was followed by a remarkable increase in the duration of the QRS interval and by a considerable delay in the intrinsicoid deflection, with secondary T-wave changes over the homolateral ventricle, in addition to a prolongation of electrical systole. These changes were characteristic of the complete type of bundle branch block. If instead of making a complete section, the upper part of the interventricular septum (where the bundle branch crosses this area) was compressed, it was observed that for short periods of time, QRS complexes were recorded similar to those of the previous experiment, the latter became progressively normal, with an intermediate stage during which a configuration similar to that of complete bundle branch block was obtained, although of shorter duration, these were designated as *incomplete bundle branch blocks*.

Notwithstanding the number of objections to the concept of bundle branch block in man, especially that of its septal mechanism, the above configurations represent, in the majority of cases, various degrees of conduction disturbance in one of the branches of the bundle of His causing ventricular asynchronism. This concept has been confirmed experimentally, pathologically, by intracavitary tracings and precordial leads, and by mechanical recordings showing ventricular asynchronism. Studies of Sodi Pallares on the mechanism of septal activation and experimental bundle branch block have contributed a great deal to a better understanding of this problem, confirming and extending knowledge of these conduction disturbances.

### VENTRICULAR ACTIVATION IN BUNDLE BRANCH BLOCK

**Right Bundle Branch Block.** In all degrees of right bundle branch block, including the complete type, the wave of excitation crosses the left septal mass, which forms the majority of the septum, following the normal pathway with no change either in direction or velocity (1,000 to 1,200 mm/sec). However, there is a late arrival of the wave of excitation to the right side of the septum, with a considerable delay (0.00 sec instead of 0.01 to 0.02 sec) after the activation of the left side. This conduction delay is due not to uniform slowing of the wave of excitation in the entire septal mass, but rather to slower progression in a

small area of the myocardium which is very close to the right surface, forming a "barrier" which separates the regions normally supplied by the left bundle branch from the area activated by the right branch. This has been proved experimentally by Sodi Pallares et al (1956) using bipolar leads, with the electrodes placed very close to one another, and including the intramural potentials.

From a vectorial point of view, four main vectors can be schematically identified in right bundle branch block representing the sequence of ventricular activation in these cases (Fig. 11-23C, D)

**Vector 1** corresponds to the normal septal vector, since this phase of the activation process is unaltered in right bundle branch block, and determines the small Q waves in leads overlying the left ventricle, as well as the small initial positive deflection obtained both in the cavity of the right ventricle and over its epicardial surface.

**Vector 2** represents the activation of the free wall of the left ventricle and is responsible for a small S wave recorded in the right ventricular cavity and over the right ventricular epicardium, since it is directed from right to left.

**Vector 3** corresponds to the powerful septal forces which are directed from left to right in the lower part of the septum, and which develop when the wave of excitation crosses the barrier between left and right septal masses with a considerable delay. This vector is of great magnitude, as it is due to a slow type of activation, and it is well known that the slower the velocity of the excitation wave, the more powerful are the corresponding vectorial forces. In view of its great magnitude, it partially neutralizes the previous one corresponding to the activation of the free wall of the left ventricle, and explains the small amplitude of these forces. The third vector is responsible for the right intracavitary R' and for most of the initial segment of the right epicardial R'.

Finally, **vector 4** probably represents a summation of the activation of the upper portions of the septum and the free wall of the right ventricle, determining the peak of R' over the right ventricular epicardium and that of S' recorded in the cavity of the right ventricle.

**Left Bundle Branch Block.** In right bundle branch block, it is difficult to detect the exact instant when the activation crosses the

ing a pseudoseptum between the aorta and pulmonary artery  
 PATROCENOSIS OF THE COARTEX. The basic anomaly may be considered to be the abnormal position of arterial trunks, together with an

absence of the ventricular septum. Hence, if there is no impediment to flow of blood, the pulmonary artery would be large and the aorta small. However, there is often an associated hypoplasia of the pulmonary tree, hence a de-

fills in the gap between the aorta and the anterior leaflet of the tricuspid.

**PATHOGENESIS OF THE COMPLEX.** We may again look upon the position of the aorta as the primary defect, with the narrowing of the pulmonary tract and the ventricular septal defect as secondary (see Chap 1). The right ventricle presents a pressure hypertrophy, since it is contracting against the combined (Lev, 1953) systemic resistance and the resistance of the pulmonary stenosis. The size of the left atrium and left ventricle is related to decreased flow.

**Partial Transposition with Aortic Hypoplasia (Eisenmenger Type).** This anomaly (Lev, 1953) resembles the Eisenmenger complex except that the aorta emerges only from the right ventricle, instead of in a straddling position (Fig 6-6C, D). The right ventricle is more hypertrophied than in the Eisenmenger complex.

**PATHOGENESIS OF THE COMPLEX** The basic anomaly again is the position of the vessels and the limited aortic tree. The right ventricle is more hypertrophied than in the Eisenmenger complex because there is more flow into the right ventricle. Even though the aorta emerges completely from the right ventricle, it does not necessarily receive blood from this chamber.

**Common Truncus from the Right Ventricle.** Here the right ventricle is more hypertrophied and the left ventricle smaller than in the overriding truncus (Lev and Saphir, 1945).

**Overriding Pulmonary Artery (the Taussig-Bing Heart).** In this complex (Taussig and Bing, Lev and Volk), the large pulmonary artery straddles the ventricular septum over a defect, thus emanating to a varying extent from both ventricles (Fig 6-7B). The small aorta emerges from the right ventricle away from the defect. The right ventricle is hypertrophied, while the left atrium and ventricle are increased in size, and hypertrophied or normal in thickness. The septal band is connected by a small ridge to the parietal band, which represents a thick bifurcated structure. One part of the parietal band passes from the septum to the anterior wall. The other part lies beneath the aorta. The coronary distribution is typical of partial transposition. Pulmonary arterial and arteriolar changes are common.

**PATHOGENESIS OF THE COMPLEX** The basic anomaly may again be considered to be the

abnormal position of vessels (see Chap 1) and their relationship to the defect. The right ventricle presents a combined pressure and volume hypertrophy due to the effects of the ventricular septal defect and the left-to-right shunt at this level. The left atrium is enlarged because of increased flow. The left ventricle may be normal or increased in size and thickness, depending upon the opposite factors of increased flow and diminished peripheral resistance. In a variant of this anomaly, there is a functional pulmonary stenosis with normal pulmonary flow.

**Complete Transposition with Normal Architecture.** In this complex (Lev, 1953; Taussig, 1938), the aorta and pulmonary artery emerge from the wrong ventricles (Fig. 6-7C). There is an associated patent foramen ovale, and there may be a ventricular septal defect or patent ductus arteriosus, instead of or in addition to the foramen ovale. The right ventricle is hypertrophied, while the left ventricle may be enlarged or normal in size. The aorta and pulmonary artery may be normal in size, but either may be larger or smaller than normal. The muscle bundles of the right ventricle may be normal in architecture, or the septal or parietal bands of the crista may be hypertrophied. The left and right coronary ostia lie in the right and left posterior sinuses of Valsalva, thus being rotated counterclockwise, looking ventricle-ward from the aorta. The coronary arteries in general take over the distribution of the opposite artery. The right auricular appendage may be displaced behind the arterial trunks.

**PATHOGENESIS OF THE COMPLEX.** The primary anomaly may be considered to be the abnormal position of the arteries. The right ventricle presents a pressure hypertrophy, being related to systemic resistance. There is usually increased pulmonary flow, hence the left side of the heart may be enlarged.

**Complete Transposition with Cor Biatritum Triloculare.** In this complex, both the aorta and the pulmonary artery emerge from a common ventricle, into which enter the mitral and tricuspid valves. The arterial trunks are in a transposed position, and either may be hypoplastic or atretic. Usually, it is the pulmonary artery which is small. There is usually a small remnant of the ventricular septum. The crista supraventricularis may be hypertrophied, form-

Fig. 11-24. Septal activation in the normal heart and in the three degrees of left bundle branch block with the corresponding ventricular complexes in the left precordial leads.

septal barrier. However, this does not apply to left bundle branch blocks, in which different types of activation are observed in relation to the degree of this conduction defect. According to Rodriguez and Sodi Pallares, three types of left bundle branch block must be distinguished (Fig. 11-24):

1. *First degree* There is only a slight delay in the spread of the stimulus in the left branch of the bundle, resulting in a *late activation of the left septal surface*, without any change in the direction or speed of the excitation wave throughout the septal mass. Since under normal circumstances, the activation of the left septal surface precedes that of the right by 0.01 to 0.02 sec, when a slight delay in the transmission of this wave occurs in the left branch (approximately 0.01 to 0.02 sec) both sides of the septum are simultaneously activated and consequently no Q wave is recorded.

2. *Second degree* In these cases, there is a greater delay of the conduction of the stimulus in the left branch, which nevertheless continues to transmit the impulse at a much lower speed. Thus, the beginning of the left septal activation is recorded with a delay of 0.04 sec and is preceded by the right septal forces. *Septal activation occurs, therefore, in an opposite direction to normal, although only partially so.*

The activation of the interventricular septum begins over the right septal surface and proceeds from right to left; if the barrier is transposed, the two septal forces will meet one another 0.04 sec later. It can be seen, therefore, that most of the septal activation proceeds from right to left, although this does not occur throughout the entire activation process, at the end of this process, late septal forces play a role and are directed from left to right. In this type of block, the Q wave, representing the normal first septal vector, disappears; there also is a slurring of the upstroke of R over the left ventricular epicardium. This represents the initial inverted activation of the septum (from right to left) and coincides with the initial r wave in the left ventricular cavity.

3. *Third degree (complete left bundle branch block)*. In this type, the left branch is completely interrupted and is functionally incapable of transmitting the excitation wave. *The right branch activates the entire septal mass in an opposite direction to normal, i.e., from right to left.* Septal depolarization is a comparatively slow process and takes place at an average speed of 300 mm/sec, which is similar to that of the spread of activation in the myocardial fibers themselves. This alone, however, does not explain the great delay of activation on the left side of the septum as compared

Fig. 11-30. Electrocardiogram of a 60-year-old patient with arteriosclerotic heart disease, showing complete left bundle branch block in the upper tracing. Bilateral internal thoracic artery ligation was performed for the relief of angina pectoris in June, 1958. In May, 1959, the patient sustained an acute coronary thrombosis; the ECG recorded 4 weeks later (lower tracing), shows deep S waves not previously present in leads  $V_3$  and  $V_6$ , probably because of the transmission of the left intracavity potential (RS) to the exploring electrode through the area of necrosis.

have been reported in the course of *digitalis* intoxication (Benchinol, 1944). It is possible that these cases may be due to a vagal influence, although it is believed by most authors that a direct toxic effect on the conduction tissue, such as occurs in cases of *myocarditis*, is probably responsible.

In clinical practice, when an intermittent type of bundle branch block is recorded, it often appears or disappears following physical

effort, amyl nitrite inhalation, or atropine injection.

Vagal stimulation obtained by ocular compression may cause the block to disappear, as in Fig 11-31. This is not a direct vagal effect upon the bundle branch, but rather an indirect

of the bundle branch system.

These types of intermittent bundle branch

with the right (approximately 0.07 to 0.08 sec)

According to Sodi Pallares (1956), the inverted activation of the interventricular septum is retarded at

the left bundle branch block, there is a delay at the opposite direction to that normally occurs. Finally, the third delay occurs upon arrival of the activation wave at the left septal surface, which acts as a second barrier. These points of delay explain both the widening of the QRS complexes and the slurring and notching of its various components which are characteristic of the complete left bundle branch block. In all degrees of left bundle branch block, notwithstanding the marked alterations in septal activation (which is not only delayed but often completely inverted in direction), the activation of the free wall of the left ventricle remains unchanged, although it begins later than normal, because of the delay that occurs in the interventricular septum.

It has not been possible to confirm the above-mentioned concept of these partial types of left ventricular conduction defect by the vectorcardiographic analysis of the incomplete types of left bundle branch block. In cases with electrocardiographic signs suggestive of incomplete left bundle branch block, the horizontal plane ECG has shown a counterclockwise rotation.

## THE ELECTROCARDIOGRAM IN BUNDLE BRANCH BLOCK

The general characteristics of the bundle branch blocks consist of widening of the QRS complexes with slurring and notching of its various waves, delay of the intrinsincoid deflection in leads corresponding to the homolateral ventricle, prolongation of electrical systole, and secondary T-wave changes. It is to be emphasized that in addition to the characteristic contours of the electrocardiogram, the practical diagnosis of right or left bundle branch block requires certain data for a more precise recognition of those conduction defects, such as a supraventricular pacemaker, a P-R interval above 0.12 sec, and a typical configuration in the precordial leads. Thus, the diagnosis of bundle branch block cannot be made in the presence of complete AV block, on the other hand, a P-R interval below 0.12 sec with a widened QRS complex usually corresponds to the Wolff-Parkinson-White syndrome. A com-

plete set of precordial leads usually permits a precise identification of the bundle branch involvement, which is often difficult on the basis of the standard leads alone, especially in cases of left bundle branch block in vertical hearts, or right bundle branch blocks in horizontal hearts.

All types of bundle branch block may be permanent or intermittent, in the latter group are included cases in which the conduction defect is transient, with normal and aberrant QRS complexes recorded in the same tracing.

In some instances, the electrocardiogram may show alternating complete and incomplete bundle branch block, a fact in favor of the general concept of the incomplete types of conduction defect.

**Complete Right Bundle Branch Block.** In right bundle branch block, the initial septal vectors are directed from left to right (as in the normal heart) and the main abnormality occurs in the final vectors. The study of the unipolar, epicardial, and intracavitary potentials in right bundle branch block has led to a better understanding of the changes observed in standard and precordial leads.

Intracavitary leads in right bundle branch blocks were recorded by Sodi Pallares et al. (1948b), in dogs as well as in human beings, and the configurations obtained corresponded to those calculated by the vectors of cardiac activation. Thus, in the right ventricular cavity, rSR' complexes were recorded, whereas in the left ventricle, the tracing was essentially a QS wave with notching and slurring of the descending limb (Fig. 11-25).

An important point to remember is that a part of the free wall of the right ventricle corresponding to the trabecular zone is very thin and rarely exceeds 2 mm, leads  $V_2$  and  $V_3$ , which usually overlie this area, record potentials closely resembling those of the right ventricular cavity. This configuration is generally rSR', which is explained by the direction and magnitude of the main vectors of the right bundle branch.

reference to the activation of the free wall of the right ventricle corresponding to leads  $V_1$  and  $V_2$ , the configuration is rSR', with a notching of the upstroke of the R' wave. This shows the great delay in the intrinsincoid deflection over the right ventricular activation which occurs in right bundle branch block.

The r and s waves correspond to vectors 1 and 2 and coincide with the two initial intracavitary deflections. The initial portion of R' is due to the

blocks, clinically observed, may appear gradually, resembling those obtained experimentally; a number of transitional complexes of incomplete bundle branch block are recorded preceding the final appearance of the complete block. These tracings, oc-

casional bundle branch block as previously described. Occasionally, normal conduction alternates with bundle branch block, either regularly (2:1; 3:1; 3:2, etc.) or irregularly, without any apparent cause. Such tracings are usually designated as *intermittent bundle branch block* and offer a unique opportunity for the study of the secondary changes in ventricular repolarization.

### BUNDLE BRANCH BLOCK AND MYOCARDIAL INFARCTION

The association of bundle branch block with myocardial infarction is not rare, although certain types of block may obscure the electrocardiographic recognition of infarction. The problem differs according to the type of block.

In *right bundle branch block*, the evidence of an associated infarction is not difficult to determine. This has been shown experimentally in dogs by cutting the right bundle branch and ligating the anterior descending branch of the left coronary artery. The tracings obtained in human beings are essentially similar to those of-

and aVF, in addition to the characteristic right bundle branch block pattern in precordial leads. As for the evidence of injury and ischemia, they are important diagnostically only during the early phase of infarction and, in the course of time, may show S-T-segment changes and other abnormalities in the absence of infarction.

according to the site of necrosis (in the free walls of the ventricles). These studies have shown that abnormal Q waves in leads  $V_1$  and  $V_2$  denote an infarct of the middle third of the septum, whereas similar deflections in  $V_3$  and  $V_4$  indicate low septal infarctions. Deep Q waves in leads  $V_5$  and  $V_6$  are characteristic signs of involvement of the free wall of the left ventricle. When the infarct is located in the free wall of the right ventricle or in the upper part of the septum, there are no definite electrocardiographic signs that can be considered diagnostically significant. Some types of infarction included in this classification correspond to a combination of those previously described.

It should be emphasized that cases of right bundle branch block with right atrial dilatation often exhibit in leads  $V_1$  and  $V_2$  a qR configuration with a delayed intrinsic deflection, which may lead to the erroneous diagnosis of right bundle branch block complicated by anteroseptal infarction. The differential diagnosis is established by the clinical data, by the progressive S-T changes, and possibly by the presence or absence of Q waves in left precordial leads, since in cases of midseptal infarction the disappearance of the initial septal vector results in the absence of Q waves in left precordial leads.

In the presence of left bundle branch block, the electrocardiogram seldom shows signs diagnostic of myocardial necrosis. This is explained by the fact that in left bundle branch block, the initial vectors of ventricular activation are fundamentally altered in direction and the septum is depolarized in a direction opposite to the normal, i.e., from right to left, causing an abnormal, initial positivity in the left ventricular cavity. Thus, it is impossible to diagnose a necrosis of the free wall of the left ventricle because the cavity potentials are transmitted to the epicardial surface through the "electrical window" and r waves are re-

duced with Q or QS waves due to transmission of the initial negativity of the left ventricular cavity to the epicardial surface over the region of the infarct. This is because in right bundle branch block, there is no change in the initial vectors of ventricular activation. Thus, the left ventricular cavity maintains its negativity, which, in cases of localized necrosis of the anterior or posterior wall, is transmitted to the epicardial surface. In *anterior infarcts*, the diagnosis is based upon abnormal Q waves in precordial leads. In *anteroseptal lesions*, these deflections are seen in leads  $V_1$  to  $V_4$  and the rS configuration is changed to QR with an increased duration of the Q wave (Fig. 11-33C). In *anterolateral infarctions*, the abnormal Q waves are recorded in the left precordial leads, and often in leads I and aVL (Fig. 11-29). Finally, in *posterior infarctions*, the diagnosis is based upon abnormal Q waves in leads II, III,

Fig. 11-25. Intracavitary and epicardial potentials in right bundle branch block.

third cardiac vector, which is the second septal vector. This is demonstrated by the fact that the notching of the epicardial R' is simultaneous with the peak of the intracavitary R' (Fig. 11-23C, D). Finally, the peak of the epicardial R' marks the arrival of the wave of excitation on the surface of the right ventricle and corresponds to the right intracavitary S wave. In other portions of the right ventricle corresponding to precordial leads V<sub>3</sub> and V<sub>4</sub>, RS complexes are obtained with a notch on the ascending limb of the R wave. This deflection is also partially due to low septal vectors located in the right portion of the septal mass, since this configuration cannot be explained on the basis of the above four vectors. This has been emphasized by Sodi Pallares, who called attention to the fact that these R waves disappear in infarctions of the lower part of the septum.

Over the epicardium of the left ventricle, QRS complexes are recorded, the initial negative deflection is due to septal activation from left to right, the R wave represents the activation of the free wall of the left ventricle (vector 2), and the S wave is generally widened and slurred, corresponding to vectors 3 and 4, which point away from the exploring electrode.

In right bundle branch block, as shown above, the main abnormalities are those of the *late vectors*, which explains the slurring at the end of the QRS complexes in lead I and left precordial leads and the late R in aVR and in the right precordial leads, since the first vectors are directed from left to right, as in normal individuals, the q waves are present in lead II and over the left precordium, whereas the right precordial leads usually show an initial positive deflection.

On the basis of these data, the configuration of the various leads in right bundle branch block is easily understood.

**STANDARD LEADS.** The QRS complexes show (Fig. 11-28A) notching and slurring with a duration of 0.12 sec or more, a widened S wave in lead I, usually smaller than the preceding R wave, is one of the main characteristics of this type of block; the q wave is usually present in this lead but may not be observed in certain cases. In lead III, the main deflection of the QRS complex varies according to cardiac rotation, it is negative in the horizontal hearts and positive in the vertical hearts. Several associated factors may change the configuration of the right bundle branch blocks in standard leads, particularly ventricular hypertrophy, myocardial disease, and the electrical position of the heart. On the basis of the variations in configuration of the QRS complex in these leads, Bayley and Wilson et al. (1932) described several varieties of right bundle branch block which were subsequently thought to have different prognostic implications (Wilbur et al., 1941).

From a practical standpoint, the most common variety of right bundle branch block is the so-called *Wilson type of block* or *wide S<sub>1</sub> variety*. It is characterized in lead I by a small initial q wave followed by a distinct, narrow R wave and a wide slurred S wave, with a positive T wave. In lead III, there is an rS complex or a deep Q wave with upright T in the horizontal heart, whereas in the vertical heart, the main QRS deflection is positive in lead III and is followed by a negative T wave. This variety of right bundle branch block is found in several types of heart disease, especially in chronic coronary insufficiency, but it may also occur in apparently normal individuals.

The so-called *rare type of right bundle branch block* shows a small r in lead I (which may be absent in some cases), followed by a deep and wide S wave, while in lead III, the main QRS deflection is positive. The T wave in these leads is in the opposite direction of the QRS complex. This type of right bundle branch block is often seen in right heart disease, suggesting the association of right bundle branch block with right ventricular hypertrophy.

A relatively rare variant of the Wilson type of right bundle branch block is the so-called *concordant inverted type*, in which wide S waves are present in the three standard leads (S<sub>1</sub>, S<sub>2</sub>, S<sub>3</sub>).

Another type of right bundle branch block shows a wide, notched R wave in lead I, with or without an S wave and left axis deviation; the precordial leads are typical of right bundle branch block. This type is not rarely encountered in cases of arteriosclerotic heart disease, but is especially common in Chagas' disease (Benchimol et al., 1954), where right bundle branch block is an exceedingly frequent finding. However, vectorcardio-

**Fig. 11-31.** Electrocardiogram of a 67-year-old female with hypertensive and arteriosclerotic heart disease and angina pectoris of 2 years' duration. Note the initial complexes in each lead showing a normal intraventricular conduction. This was obtained by a slight slowing of the cardiac rate as a result of ocular compression. The last QRS complexes in every lead exhibit a configuration of complete left bundle branch block. In lead II, ventricular premature beats with a bigeminal rhythm are recorded.

corded instead of the typical Q waves which denote infarction. However, in the early stages of the coronary attack, the diagnosis of myocardial infarction associated with left bundle branch block may be suggested by ST-T and T-wave changes due to injury and ischemia, especially in cases that have a suggestive clinical history and in the presence of serial tracings.

When the infarct involves the *septal mass*, the initial negativity of the right ventricular cavity is transmitted to the left and is recorded through the infarcted area in left precordial leads, and occasionally in lead I. Thus, the presence of a Q wave in leads I, V<sub>5</sub>, and V<sub>6</sub> in a case of left bundle branch block usually denotes an associated *septal infarction* (Fig. 11-33D). The observation of RS com-

plexes in leads V<sub>7</sub> and V<sub>8</sub> was suggested as a sign of *lateral wall infarction* in cases of left bundle branch block because of the recording of left intracavitary potential (RS) over the epicardial surface of the left ventricle through the area of myocardial necrosis (Fig. 11-30). It must be emphasized, however, that this configuration may also be recorded at the transitional zone if the latter is displaced to the left, as in a horizontal heart with a clockwise rotation.

It should be emphasized that Q waves may be present in leads I, V<sub>5</sub>, and V<sub>6</sub> in cases of left bundle branch block without myocardial infarction. There are several possible interpretations for these initial negative deflections. (1) recording of left atrial potentials in horizontal hearts with marked clockwise rotation; (2) associated right

graphic studies seem to indicate that these cases correspond to left bundle branch blocks associated with extensive septal and inferolateral infarctions. The standard leads in right bundle branch block also show secondary changes of the repolarization process, with asymmetric T waves in the opposite direction of the major deflection of the QRS complex, thus, they are usually positive in lead I, in view of the marked widening of the S wave, and negative in lead III. The electrical axis of the T wave (AT) is usually deviated to the left, as opposed to the right axis deviation of the QRS complex.

**UNIPOlar LIMB LEADS** The configuration of aVL and aVF varies according to the electrical position of the heart, although in aVR there is always a late, slurred R wave (Fig. 11-28A). This deflection is due to the late activation of the right ventricle from left to right, upwards and anteriorly (vector 4), in the direction of the right arm. The QRS complexes are similar to those obtained in the right atrial cavity, whereas those of aVL and aVF resemble the left ventricular precordial leads.

**PRECORdIAL LEADS** In the right precordial leads ( $V_1$  and  $V_2$ ), the ventricular complexes are usually of the rsR' type with variations in the amplitude of the deflections from one case to another, involving particularly the first two waves of the QRS complex. Occasionally, the S wave does not reach the base line and the configuration becomes rR'. The peak of the R' wave corresponds to the arrival of the wave of excitation over the right ventricular epicardial surface and is always delayed. Very often, there is a notch on the ascending limb of R' which marks the end of septal activation and the beginning of depolarization of the free wall of the right ventricle (Fig. 11-23C, D), this was demonstrated by simultaneous recordings of precordial and right ventricular intracavitary leads.

Since the beginning of septal activation is unchanged in right bundle branch block and is directed from left to right, the QRS complexes are almost always initially positive. However, the absence of an initial r wave in  $V_1$  does not necessarily represent an associated antero-septal necrosis, it may be due to either a perpendicular direction of the first vector to lead  $V_1$ , or an enlarged right atrium which transmits its potential to lead  $V_1$ .

With reference to ventricular repolarization, secondary inversion of the T wave is often seen, with a depressed S-T segment in leads  $V_1$  and  $V_2$ .

In the left precordial leads ( $V_5$  and  $V_6$ ), the QRS complexes are usually of the qRS type, similar to lead I, with a wide and slurred S wave (Fig. 11-28A). In the absence of an associated left ventricular hypertrophy, there is no delay in the intrinsoid deflection. The T waves are generally positive, if they are negative, this suggests

Fig. 11-26. Right bundle branch block in various types of heart disease (precordial leads).

myocardial ischemia or left ventricular hypertrophy.

In the intermediary points over the precordium (between leads  $V_1$  and  $V_2$ ), it is not unusual to record QRS complexes which resemble those of the right intracavitary leads (rsR'S'), probably corresponding to the thin trabecular zone of the free wall of the right ventricle. In leads  $V_3$  and  $V_4$ , an RS configuration is frequently obtained with a notch on the ascending limb of the R wave. These waves are probably due to the low septal vectors pertaining to the right ventricular portion of the septum, as previously described (Fig. 11-23).

In the following types of heart disease with right bundle branch block, certain configurations of the precordial leads are often of diagnostic importance (Fig. 11-26):

1. In *arteriosclerotic and hypertensive heart disease* it is not unusual to record qRS complexes from leads  $V_3$  to  $V_6$ , suggesting that the potentials of the hypertrophied left ventricle are transmitted to all leads which are to the left of  $V_3$ .

2. In *atrial septal defect (ASD)*, qR complexes are often obtained in lead  $V_1$ , because of right atrial enlargement, whereas the remaining precordial leads ( $V_2$  to  $V_6$ ) show right ventricular potentials, initially ( $V_2$  and  $V_3$ ) recording the potential variations or the free wall, then those of the trabecular zone ( $V_4$  and  $V_5$ ), and finally those of the right side of the septum ( $V_6$ ).

3. In *Ebstein's disease*, the potentials of the right atrium (qR) are recorded in leads  $V_3$ R,  $V_1$ ,  $V_2$  and occasionally extend to other precordial leads. The left ventricular potentials

Fig. 11-32. A left bundle branch block. Note in lead I a transitional complex with the configuration of incomplete left bundle branch block, followed by a QRS complex with normal intraventricular conduction (the last complex in lead I). In the remaining leads the ECG shows incomplete left bundle branch block. B: Second-degree incomplete left bundle branch block in a 65-year-old patient with hypertensive and arteriosclerotic heart disease.

(qRS) are recorded in leads  $V_4$  to  $V_6$ . Only occasionally are the right ventricular potentials obtained from the trabecular zone in lead  $V_3$ . Thus, in Ebstein's disease, the dominant electrocardiographic signs are those due to the right atrium and left ventricle, with a limited area of right ventricular complexes over the precordium.

4. In *Eisenmenger's syndrome*, leads  $V_3$  to  $V_6$  reflect the potential variations of the lower part of the septum, whereas leads  $V_1$  and  $V_2$  record rsR' complexes from the free wall of the right ventricle. Left ventricular configurations (qRS) are occasionally seen in lead VF.

**Complete Left Bundle Branch Block.** When the left branch of the bundle of His is incapable of transmitting the cardiac stimulus, the entire septum is activated from right to left and the initial vectors become definitely abnormal. As a result, the q wave disappears in all leads which reflect the potentials of the left ventricle. In addition, there are an increased duration and a change in configuration of the QRS complexes, which become widened, slurred, and notched.

These abnormalities can be attributed to the three main points of delay in the spread of the stimulus throughout the septal mass, as previously discussed with reference to cardiac activation in left bundle branch block.

A comparison of the unipolar epicardial configuration with the intracavitary leads is important in order to understand and interpret the standard and precordial leads. According to the experimental work of Sodi Pallares et al. (1950), in the intracavitary lead of the left ventricle, the form of the QRS complex varies from one point to another, in the lower part

of the cavity, RS complexes are obtained, whereas the upper posterobasal portions show a qR configuration. The presence of a q wave in those leads is presumably due to the first septal vector, which is oriented from right to left, downwards, and slightly anteriorly; it is also possible that the lower part of the right aspect of the septum may contribute toward this deflection. This configuration is important for the diagnosis of infarcts involving the middle third of the septum, since in these cases, instead of RS complexes in the lower part of the left ventricular cavity, the tracing shows qR deflections resembling those of the posterobasal intraventricular leads. The S wave, which may be recorded in the cavity of the left ventricle, is probably due either to the activation of the upper part of the septum or to that of the free wall of the left ventricle.

In the cavity of the right ventricle, the configuration of left bundle branch block is essentially negative (QS), with notching and slurring of the QRS complexes.

Certain aspects of the epicardial leads in relation to the intracavitary potentials need further discussion (Fig. 11-27A). In the epicardial leads over the right ventricle, the R waves are often absent from  $V_1$  to  $V_4$ , in view of the fact that the right-to-left septal vector is of great magnitude and neutralizes those of the free wall and the lower septal portion of the right ventricle. In the leads over the left ventricle ( $V_5$  and  $V_6$ ), the ascending limb of the R wave is probably due to the spread of the stimulus through the barrier, whereas the slurring of the "plateau" of the QRS complex corresponds to the activation of the septum from right to left; finally, the last peak of the

ventricular hypertrophy; (3) right intraventricular conduction defect (Laham, 1952).

Certain cases of left bundle branch block show Q waves in leads I, V<sub>5</sub>, and V<sub>6</sub> in the absence of myocardial infarction. This is because of one of the following possibilities: (1) recording of left atrial potentials over the pre-

cordium in horizontal hearts with marked clockwise rotation; (2) associated right ventricular hypertrophy; or (3) right intraventricular conduction defects.

Cabrera and Friedland (1953) called attention to the importance of a late notching of the S or QS wave in leads V<sub>3</sub> and V<sub>4</sub> as a strong indication of myocardial necrosis in the

**Fig. 11-33.** A. Complete left bundle branch block in a 42-year-old patient who was asymptomatic and showed a normal heart size on roentgenologic examination B. Right bundle branch block and anteroseptal infarction C in a 45-year-old patient. ■ Complete left bundle branch block and anterior wall infarction with septal involvement, recorded during the acute and subacute stages of coronary occlusion. Observe ST-T changes and the deep Q waves in leads I, aVL, and V<sub>6</sub> indicating myocardial necrosis E Left bundle branch block and anterior wall infarction showing a late notch on the ascending limb of the S waves in leads V<sub>3</sub> to V<sub>4</sub>. This case had autopsy confirmation.

R wave is due to the depolarization of the free wall of the left ventricle. Actually, it is not known exactly where the septal activation ends and that of the free wall of the left ventricle begins.

**STANDARD LEADS.** The QRS complexes are notched, slurred, and widened, with a duration of 0.12 sec or more (Fig. 11-28B). There are no q or S waves in lead I, and the mean electrical axis of the QRS complex (AQRS) is deviated to the left from 0 to  $-75^\circ$ . In rare cases, the electric axis is within normal limits, and under unusual circumstances, a right axis deviation may be present.

The presence of a q wave in lead I would suggest a previous septal infarction, post-infarctional block, respiratory variations of cardiac position, or other factors, including right ventricular hypertrophy.

The variations of AQRS in left bundle branch block are due to several factors, such as left ventricular hypertrophy, the location and extension of coexistent myocardial lesions, and especially the position of the heart in the chest. The conduction types and those with right axis deviation are generally found in vertical hearts.

The T waves are asymmetric and opposed to the major deflection of the QRS complex, this is also observed with reference to the S-T segment.

**UNIPOLAR LIMB LEADS.** The patterns obtained in these leads are essentially dependent upon the electrical position of the heart. Since left bundle branch block is mostly seen in horizontal hearts, lead aVL records left ventricular potentials and is similar to leads I,  $V_5$ , and  $V_6$ . In some of these cases, a small q wave may be recorded in these leads in the absence of anteroseptal infarction. In lead aVF, the ventricular complexes are of the rS or QS types, a fact which is not due to myocardial necrosis. Lead aVR shows variable configurations (rS, QS, QR), according to the position of the QRS axis, and generally resembles the right atrial intracavitary lead.

In the unusual cases occurring in vertical hearts, aVF records left ventricular potentials and aVL faces the right ventricle, whereas aVR is variable and depends upon the degree of right axis deviation. This electrical position is responsible for patterns simulating right bundle branch block in the standard leads, although the precordial configurations are typical and diagnostic.

**PRECORDIAL LEADS.** In leads  $V_5$  and  $V_6$  corresponding to the left ventricle, essentially positive QRS complexes are obtained with an initial, slurred R wave of variable amplitude (Fig. 11-28B). Following this deflection, there is always a notched plateau which extends to the peak of a rapid and

delayed intrinsically deflection; in certain cases, these complexes assume an M-shaped configuration. There is, as yet, no complete agreement as to the correct interpretation of the plateau.

It is to be emphasized that in hearts with marked clockwise rotation, these QRS complexes are observed only in lead  $V_1$  (or farther to the left), which may suggest an associated right ventricular enlargement. The T waves are negative, with an S-T segment depression and an upward convexity of the S-T segment; these repolarization changes are secondary to the QRS abnormality.

In leads over the right ventricle ( $V_1$  and  $V_2$ ), the tracing does not show remarkable changes, as it begins with a small r wave and ends with a wide and deep S wave. The persistence of the initial r wave in the left bundle branch block, in the presence of an inverted septal activation, is probably explained by early activation of the free wall of the right ventricle, in addition to that of the lower portions of the septum pertaining to this ventricle. Very often, however, this small r wave disappears, and QS complexes are recorded in the right precordial leads, suggesting the presence of anteroseptal infarction. In these cases, the negativity is explained by a neutralization of the lower septal vectors and those of the free wall by the more powerful septal forces directed from right to left. The T waves are positive in these leads, with elevated S-T segments.

**Ventricular Repolarization in Left Bundle Branch Block.** Under normal circumstances, the repolarization process of the free wall of the left ventricle dominates that of the interventricular septum, and explains the negative T wave in the ventricular cavity with an up-right deflection over the epicardial surface. This is because, in man, repolarization proceeds in an opposite direction to that of depolarization (Fig. 11-27C and D). In left bundle branch block, septal repolarization is greater than that of the free wall and is directed from right to left, although the vector is conventionally represented in the opposite direction. This explains the negative T wave both in the cavity and over the left ventricular epicardium. Consequently, septal repolarization is mainly responsible for the T wave changes in left bundle branch block.

## INCOMPLETE BUNDLE BRANCH BLOCK

The concept of "incomplete" bundle branch block presupposes a delay in conduction through one of the branches of the His bundle, although the excitation wave is not entirely

## BUNDLE BRANCH BLOCK 11-81(Supp.)

presence of left bundle branch block (Fig. 11-33E).

Sodi Pallares et al. (1957) described eight varieties of infarction complicated by bundle branch block, which could be distinguished electrocardiographically on the basis of the modern concepts of ventricular activation and the identification of the intracavitary potentials. It was shown by these authors that in bundle branch block, could be distinguished by the potentials (RS) in precordial leads  $V_1$  and  $V_2$  and the morphology in

and in cases with extension into the free wall of the left ventricle.

Most pathologic studies have confirmed the electrocardiographic criteria for the diagnosis of myocardial infarction complicated by left bundle branch block.

### THE VECTORCARDIOGRAM IN BUNDLE BRANCH BLOCK

Vectorcardiography has unquestionably played an important role in the better understanding of many obscure aspects of the ECG, particularly with reference to the intraventricular conduction defects.

Nevertheless, the subject of conduction defects has not yet been completely clarified, and there are still many controversial opinions regarding electrogenesis and the correct interpretation of many ECG tracings, as well as VCG loops. Adequate experimental data, in addition to electrovectorcardiographic correlation, are still lacking. Lately, however, important contributions have been published in the literature on this subject, and many problems have appeared requiring future investigation.

The VCG is very useful in the diagnosis of the more advanced forms of bundle branch block. Interpretation of the lesser degrees of these conduction defects is still controversial, and, at present, it is difficult to distinguish certain cases of ventricular hypertrophy from the so-called incomplete types of bundle branch block.

As previously mentioned, the electrocardiographic diagnosis of bundle branch block is based upon certain findings, such as atrioventricular conduction, abnormal slurring and notching of the QRS complexes, and a late R wave in the unipolar leads facing the ventricle on the side of the blocked bundle branch.

Atrioventricular conduction cannot be demonstrated in the VCG, it is necessary to record the ECG for this purpose. With reference to notching and slurring, the VCG is a more adequate tracing, since it distinguishes the true from the false types of slurring. True slurring is due to a slow inscription of the spatial vectors, and it is observed in the various planes, the false types of slurring result from the perpendicularity of certain portions of the VCG loop in relation to one of the planes, and are therefore limited to this plane.

Finally, the late R wave corresponding to the ventricle with delayed activation is shown in the VCG by a loop which points toward this ventricle. As a rule, the main vectorcardiographic features of bundle branch block are the slow inscription of certain portions of the loop, the direction of the initial part of the loop, and frequently the type of rotation in the horizontal plane (Grishman and Scherlis, 1952).

**In Complete Left Bundle Branch Block.** The main VCG features of complete left bundle branch block are as follows (Fig. 11-34).

Fig. 11-34.

# 11-72(Supp.) RATE, RHYTHM, AND CONDUCTION DISTURBANCES

arrested as in the "complete" types of block. Thus, the activation of each ventricle in the incomplete bundle branch blocks proceeds through its corresponding branch, though with a variable degree of delay.

This interpretation was accepted following the investigations of Wilson and Herrmann, which were later confirmed and extended by Sodi Pallares (1950), in addition to the clinical observation of tracings similar to those experimentally obtained

The fact that both clinically and experimentally, continuous tracings were obtained show-

ing QRS complexes intermediate in configuration between normal records and complete bundle branch block (Fig 11-32A) seems to confirm the actual existence of incomplete bundle branch block, which has been such a controversial subject among the various investigators.

From the morphologic standpoint, these tracings resemble complete bundle branch block, although the duration of the QRS complexes is less than 0.12 sec (usually between 0.10 and 0.12 sec). However, Sodi Pallares attaches greater importance to the morphologic

Fig. 11-28. A. Complete right bundle branch block in a 29-year-old patient with interatrial septal defect B. Complete left bundle branch block in a 60-year-old patient with arteriosclerotic heart disease.

1. Changes in the spatial QRS loop. In the horizontal plane, the initial portion of the loop (Q loop) decreases, and is slowly inscribed, oriented usually forward and slightly to the left; in some cases, however, it is directed posteriorly and to the left, and very rarely anteriorly and slightly to the right. Whatever its initial direction, the QRS loop, sometimes after a sharp angulation, is rapidly inscribed posteriorly and to the left (R loop) with a clockwise rotation, which is the main VCG feature of this type of block.

The long axis of the loop usually lies between  $-30$  and  $-60^\circ$  in the horizontal plane. In the afferent limb, or more frequently in its middle portion, there is evidence of conduction delay, as shown by the closer proximity of the time markings. At this point, there is an irregularity of the loop, constituting a "plateau," the duration of which is proportional to the degree of block (Fig. 11-35).

Occasionally, the VCG in the horizontal plane is characterized by a "figure-8" type of rotation, with an initial counterclockwise direction followed by a clockwise inscription; in

these cases, the Q loop is usually directed anteriorly and to the left.

The QRS sE usually fails to close prior to the inscription of the T sE loop, this is because it does not return to its point of origin, so that the J point is deviated to the right and anteriorly, resulting in an ST vector pointing in the same direction.

In the frontal plane, the QRS sE loop of the VCG is inscribed counterclockwise (with very rare exceptions), to the left, and superiorly. The loop is usually open, with an ST vector pointing downward and to the right.

In the sagittal plane, it is important to note the clockwise rotation of the loop, with its main axis pointing posteriorly and slightly superiorly or inferiorly. The loop fails to close as in the other planes, with an ST vector pointing anteriorly and slightly inferiorly.

2. Spatial T Loop (T sE). The T sE loop is usually oriented opposite the QRS sE loop, to the right, anteriorly and superiorly or inferiorly.

In *Incomplete Left Bundle Branch Block*. The vectorcardiographic criteria of incomplete left bundle branch block are much less precise

Fig. 11-35. Complete left bundle branch block in a 29-year-old male with Chagas' heart disease. The VCG shows the typical clockwise rotation in the horizontal plane with a delay in the middle portion of the loop.

criteria than to the delay of the intrinsinoid deflection, accepting as incomplete bundle branch blocks even cases with a normal QRS duration (less than 0.10 sec).

**Incomplete Right Bundle Branch Block.** This type includes electrocardiograms with an rSR' configuration in the right precordial leads, with variable amplitudes of the individual deflections, and a total duration of the QRS complexes below 0.12 sec. Although the intrinsinoid deflection is inscribed with a delay of 0.04 to 0.06 sec, the marked delay observed in incomplete right bundle branch block is not seen in these cases. In the standard leads, the tracing may be normal, although there often is a slurred S wave in lead I and a late wide R wave in lead III.

This type of electrocardiogram is frequently observed in normal individuals, although it is especially common in diseases affecting the right heart (atrial septal defect, tricuspid insufficiency, etc.). Although Sodhi-Pallares et al. (1950) consider this configuration as due always to a right bundle branch conduction defect, Kossmann et al. (1950) admit the possibility of a late activation of the crista supraventricularis of the right ventricle, both in normal individuals and in some persons with right ventricular hypertrophy.

From a practical standpoint, it is obvious that not all tracings with this configuration actually represent incomplete right bundle branch block. However, it is extremely difficult to distinguish the true incomplete right bundle branch block from similar tracings which correspond to normal variants, or those due to right ventricular hypertrophy, although several criteria have been suggested to differentiate these conditions. The most important practical contribution to this problem has been that of vectorcardiography in clarifying certain aspects of the rSR' configuration in  $V_1$ .

**Incomplete Left Bundle Branch Block (Fig. 11-24).** The first-degree left bundle branch block is characterized by an absence of q waves in leads  $V_1$  and  $V_2$ , which is not in itself sufficiently diagnostic, since this may occur in normal individuals with vertical heart and a clockwise rotation. However, the presence of an initial slurring of the R wave in these leads is of greater diagnostic importance, since it represents bilateral septal forces which neutralize each other. The T waves are either normal or slightly decreased in amplitude.

In second-degree left bundle branch block, septal activation is partly inverted, the majority of the septal mass being activated from right to left. Only a small portion of the left side of the septum is activated by late forces directed from left to right. In these cases, Q waves are absent in leads  $V_1$  and  $V_2$  and there is a slurring of the entire upstroke of the R wave. The duration of the QRS interval is slightly greater than that of first-degree bundle branch block, and the T wave becomes negative because of the inverted direction of septal repolarization (Fig. 11-32B).

In contrast to the incomplete right bundle branch block, which may occur in normal hearts, in the majority of cases, incomplete left bundle branch block denotes organic heart disease with left ventricular hypertrophy. The occurrence in continuous tracings of complete and incomplete left bundle branch block alternating with a normal QRS complex constitutes important evidence in favor of the incomplete bundle branch block concept, which is still denied by some authors.

## BUNDLE BRANCH BLOCK AND VENTRICULAR HYPERTROPHY

The configuration of right bundle branch block, especially of the incomplete type, is often seen in certain types of right heart disease, such as atrial septal defects, tricuspid insufficiency, etc., and has been described by Cabrera and Monroy as evidence of diastolic overload of the right ventricle. Although this is true in most cases, it should be emphasized that similar electrocardiograms may be observed in normal hearts and in cases of true right bundle branch block. The distinction between these three conditions is difficult from an electrocardiographic standpoint, and it is often necessary to base the interpretation upon clinical data and on other abnormalities of the tracing (P pulmonale, Lewis index, right axis deviation, etc.). Vectorcardiography is of great help, because the orientation of the loop in the horizontal plane is frequently diagnostic and differs in right ventricular hypertrophy from that in normal hearts and in right bundle branch block.

It is well known that left bundle branch block usually coexists with left ventricular hypertrophy. According to most authors, the latter is practically inferred in the presence of this type of conduction defect; however, there are

Fig. 11-36.

than those of the complete type. Very often, the VCG in incomplete left bundle branch block is similar in configuration to that of complete left bundle branch block, with the exception of its duration (less than 12 sec) and the lesser degree of slowing observed in the middle portion of the loop (first- and second-degree left bundle branch block) (Fig. 11-34).

In certain instances, the slowing of the middle portion does not occur, but the loop is inscribed in a clockwise direction in the horizontal plane; this is an important distinguishing feature from simple left ventricular hypertrophy.

The QRS sE loop in the horizontal plane is frequently inscribed to the left and posteriorly, initially with a counterclockwise rotation, followed by a clockwise rotation which may occur at different points of the loop, near its middle portion or not. In these cases, the loop has a characteristic figure-8 type of configuration with a slow inscription of its initial portions, with or without an additional delay in the middle portion of the loop.

Finally, in certain instances of incomplete left bundle branch block, the middle portion of the horizontal QRS loop shows either a slight slowing or a counterclockwise rotation, although a certain delay in the initial portion of

the loop is observed, it is difficult to distinguish these types of VCG from those of left ventricular hypertrophy.

**In Right Bundle Branch Block.** The initial portion of the QRS sE loop is normally inscribed, i.e., to the right and anteriorly, since the initial vectors of ventricular activation remain unchanged in this type of conduction defect. The most important feature of the loop is its terminal portion, which is slowly inscribed, with an irregular contour constituting an appendage, which in the horizontal plane is directed anteriorly and to the right (Fig. 11-36). The general aspect of the loop varies in form and direction.

Two main types have been pointed out. One was described by Cushman et al. (1938), with a QRS sE loop inscribed to the left and posteriorly and a counterclockwise rotation in the horizontal plane followed by a delayed terminal appendage [Fig. 11-36(1)]. These loops correspond to the ECGs of the so-called *atypical* forms of right bundle branch block, and are often found in chronic Chagas' heart disease, AV communis, and other cardiac conditions. A second type of VCG in right bundle branch block has been emphasized by Cabrera et al. (1958), with the QRS sE loop in the horizontal plane showing an initial clockwise rotation,

a few exceptions to this rule, such as the case shown in Fig. 11-24B.

In the presence of associated bundle branch block, the classical electrocardiographic criteria for the diagnosis of ventricular hypertrophy may not apply, because of the altered pathways of ventricular activation. In such instances, the recognition of ventricular overload may be extremely difficult.

A review of the criteria proposed by a number of authors, which so far have been accepted, has shown that they cannot be used in many cases.

Many of these patterns appear in *experimental blocks*, and occasionally in a variety of clinical cases, in which the diagnosis of co-existent ventricular hypertrophy cannot be made unequivocally. On the other hand, certain cases of *transient bundle branch block* with suggestive evidence of associated hypertrophy have not exhibited any of the diagnostic criteria of ventricular overload following the restoration of normal conduction.

At present, it appears that the best criteria for the diagnosis of ventricular hypertrophy associated with bundle branch block are the following.

1. *Diagnosis of right ventricular hypertrophy in the presence of right bundle branch block*

- a. Signs of right atrial enlargement
- b. Right axis deviation exceeding  $+120^\circ$
- c. Presence of  $RR'$  in leads to the left of  $V_3$  (this is considered as evidence of right ventricular dilatation)
- d. Deeply inverted T waves in  $V_1$ ,  $V_2$ , and  $V_3$

Although, from a statistical standpoint, deep S waves in leads I,  $V_5$ , and  $V_6$ , or an R' exceeding 10 mm in  $V_1$ , occur more frequently in cases of associated right ventricular hypertrophy, these signs may also make an appearance in many cases of isolated right bundle branch block.

2. *Diagnosis of left ventricular hypertrophy in the presence of right bundle branch block*

- a. Signs of left atrial enlargement (in the absence of mitral stenosis)
- b. R waves of high voltage and a delayed intrinsicoid deflection in  $V_5$  and  $V_6$  (0.05 sec)
- c. Deep S wave preceding an R' in  $V_1$  and  $V_2$
- d. QRS axis deviated upwards and to the left in the frontal plane

- e. Presence of q waves in leads I,  $V_5$ , and  $V_6$

Other minor signs, which may be useful in some cases, are the early transition in the precordial leads and the presence of T-wave inversion in leads  $V_5$  and  $V_6$ .

3. *Diagnosis of left ventricular hypertrophy in the presence of left bundle branch block*

As previously stated, the presence of left bundle branch block in itself is considered evidence of associated left ventricular hypertrophy in view of the high statistical incidence (approximately 95 per cent) of left ventricular enlargement in cases of left bundle branch block. Nevertheless, the following signs are highly suggestive of left ventricular hypertrophy in the presence of left bundle branch block:

- a. Sokolow-Lyon index above 35 mm
- b. White-Bock index above  $+18$  mm
- c. Marked left axis deviation of the QRS complex, with right axis deviation of the T wave
- d. Tall R waves in the left precordial leads with a tendency to the disappearance of the "plateau"
- e. Signs of left atrial enlargement (an indirect sign, although one of the most important diagnostic criteria of associated left ventricular hypertrophy)

Under these circumstances, it is very difficult to identify right ventricular hypertrophy for several reasons, including the fact that these cases usually exhibit biventricular hypertrophy associated with left bundle branch block.

However, vertical electrical position of the heart, clockwise rotation, and leftward displacement of the transitional zone in precordial leads with S waves in  $V_6$  and  $V_7$  are highly suggestive of coexistent right ventricular hypertrophy (Laham, 1951, 1952).

From a vectorcardiographic standpoint, the association of right ventricular hypertrophy and right bundle branch block has been described (Burch et al., 1953, Wolff et al., 1953) as showing a displacement of the QRS loop anteriorly and to the right and as maintaining the classical VCG characteristics of right bundle branch block (delayed terminal appendage) [Fig. 11-36(2)]

Left ventricular hypertrophy in right bundle branch block displaces the loop so that it as-

followed by a counterclockwise inscription, and a preterminal delay often resulting in a figure-8 configuration [Fig. 11-36(2)]. This type is often seen in coronary heart disease.

The T loop is usually opposed to the delayed terminal appendage, and its abnormalities are less conspicuous than those of left bundle branch block. The vectorcardiographic distinction between *complete* and *incomplete right bundle branch block* is made solely on the basis of the duration of inscription, since there are no significant differences in configuration of the respective VCG loops.

The VCG has been found to be the most useful in distinguishing incomplete right bundle branch block from other tracings with an  $rsR'$  configuration in lead  $V_1$ , which correspond to either normal hearts or slight degrees of right ventricular hypertrophy.

## ETIOLOGY

*Coronary heart disease* is undoubtedly the main cause of bundle branch block, either as

an isolated factor or in association with arterial hypertension. One of the branches may be damaged by an *acute infarction*, followed by fibrosis, or by a slow and progressive *ischemia* due to chronic coronary insufficiency.

Bundle branch blocks may be found in the absence of any type of apparent organic heart disease; this is much more common in right than in left bundle branch block.

Left bundle branch blocks occur mostly in hypertensive or arteriosclerotic heart disease and in aortic valvular disease, especially in *calcific aortic stenosis* and in *syphilitic aortic insufficiency*. Less common causes are classified in Table 11-2.

Right bundle branch blocks are observed in normal persons and in a variety of organic heart diseases, and are thus commonly found in clinical practice.

In normal individuals, right bundle branch block is usually of the incomplete type, decreasing during the Valsalva maneuver and increasing during the Muller maneuver. The elec-

Fig 11-36(1). Complete right bundle branch block in a 26-year-old patient with Chagas' heart disease. The mean spatial QRS axis is at  $-150^\circ$ . The VCG shows a counterclockwise rotation in the horizontal plane, with a terminal delayed appendage pointing rightward and anteriorly.

assumes a more superior orientation as compared with its position in uncomplicated right bundle branch block (Grishman and Scherlis, 1952; Burch et al., 1953; Massie and Walsh, 1960).

An interesting type of left ventricular hypertrophy with terminal delay in intraventricular conduction has been described by Grishman and Scherlis (1952). In these cases, the ECG displays a widened QRS complex, with wide, slurred S waves in  $V_4$ , marked left axis deviation, and secondary S-T segment and T-wave changes.

The VCG in these cases shows the typical signs of left ventricular hypertrophy, with a delay in the terminal segment of the afferent portion of the QRS loop, which is oriented to the right, posteriorly, and superiorly.

## INTERMITTENT BUNDLE BRANCH BLOCK

Experimentally, a complete bundle branch block pattern may be obtained by direct percussion of one of the branches of the bundle of His (this is more easily obtained in the right bundle branch), and serial changes of the tracing are recorded. It is interesting to note then that as the conduction defect improves, the degree of block progressively decreases until normal conduction is finally restored. It is conceivable, therefore, that in the presence of an organic lesion of one of the branches of the bundle of His, the occurrence of an attack of tachycardia, or any other aggravating factor of the conduction defect, may lead to a transient block of the impulse through the damaged bundle branch. Thus, intermittent bundle branch blocks are probably more common than they appear to be statistically, and would probably be more frequently recorded if serial tracings were obtained in the initial stages of the organic bundle branch lesions. Nevertheless, numerous cases of transient bundle branch block have been published in the literature (Benichou, 1944, 1945), demonstrating that this is not a rare finding in clinical cases.

It was thought at first that this represented a purely functional disturbance; however, it is now considered to be due to lesion of the conduction tissues, frequently denoting advanced cardiac disease. The majority of the so-called "functional" bundle branch blocks is observed in the course of supraventricular tachycardia or atrial flutter or fibrillation. Although some patients with this type of block do not appear to

suffer from any cardiac disease, it is difficult to rule out minor lesions of the conduction tissues leading to fatigue of the bundle branch with a decrease in its conduction capacity in the presence of a functional strain. Many factors have been described as capable of precipitating these types of block. Thus, changes of vagal tone or of heart rate, hypoxia, heart failure, toxic processes, etc., have been considered.

Although changes in vagal tone may indirectly influence intraventricular conduction, it appears that this increased tone is not directly responsible for the prolonged inhibition of con-

duction factor, have been described (Vessell, 1951). There was a critical rate for the appearance of block, and this often disappeared following a slight decrease of rate. In other instances, the bundle branch block appears on effort or following some factor which temporarily overloads the heart in the presence of advanced pathologic changes (usually due to coronary arteriosclerosis).

In these cases, the different involvement of the two branches leads to a difference of their refractory periods. However, a normal intraventricular conduction is still compatible with a permanent increase in the refractory period predominating in one of the branches of the bundle of His. The conduction defect only appears following the influence of certain factors, which increase the refractory period or inhibit conduction completely.

Cases have been described in which bundle branch block appeared in the course of heart failure and disappeared as soon as cardiac compensation was obtained. Other instances

Fig. 11-29. Electrocardiogram of a 63-year-old male with complete right bundle branch block and anterolateral infarction; deep Q waves are recorded in left precordial leads, with the typical right bundle branch configuration maintained in leads  $V_1$  and  $V_2$ .

Fig 11-36(2). Right bundle branch block with  $\Delta QRS$  at  $180^\circ$  in a 46-year-old patient. The VCG displays an initial clockwise rotation of the loop in the horizontal plane, followed by a counter-clockwise rotation and a delay in the terminal portion.

trocardiographic and vectorcardiographic features are usually similar to those found in *pectus excavatus* and in certain *atrial septal defects* without pulmonary hypertension.

In younger patients, the main causes of right bundle branch block are *congenital heart disease*, *rheumatic heart disease*, and *Chagas' disease*.

With reference to rheumatic heart disease, right bundle branch block is usually found in the presence of mitral and tricuspid lesions. In these instances, P-wave changes diagnostic of biatrial enlargement are usually present, or atrial fibrillation, in addition to other characteristic changes of rheumatic heart disease.

In pure mitral stenosis, which exhibits a double-peaked R wave in  $V_1$ , there is usually a moderate degree of right ventricular enlargement.

In many Latin American countries, a common cause of right bundle branch block is chronic Chagas' heart disease, which shows a remarkably high incidence of this type of conduction disturbance. The ECG usually records a complete type of right bundle branch block,

with left axis deviation as a very common finding [Fig. 11-36(3)]. In serial tracings, other electrocardiographic abnormalities are often associated, such as ventricular premature beats and various types of AV block.

In congenital heart disease, right bundle branch block is frequently recorded (Table 11-3), especially in *atrial septal defects*, either as an isolated finding or associated with other cardiac malformations.

In isolated atrial septal defects, according to most authors, right bundle branch block is an evidence of *diastolic overload* of the right ventricle; in such instances, the conduction defect is either complete or, more frequently, incomplete, with right axis deviation, and, contrary to the situation in coronary cases, very seldom shows a counterclockwise rotation. The P-wave changes are usually more marked than those observed in coronary insufficiency, although of a lesser degree than those exhibited by mitro-tricuspid patients.

The problem of right bundle branch block, and especially that of a double-peaked R wave in right precordial leads, is of great interest

PATIENTS OR THE CONTRARY. The displaced tricuspid orifice may be considered to be the basic anomaly. Thus, the right atrium and proximal part of the right ventricle act as a unit, although the exit method of their functioning is not clear. There is usually decreased pulmonary flow. If there is a functional tricuspid stenosis, then there is a venous shunt at the atrial level, and hence the left atrium and ventricle may present a volume hypertrophy, if not counterbalanced by the decreased pulmonary flow.

**Hypoplasia of the Aortic Trunc Complexes.** In this group (Lev, 1973) the following common demonstrable exist (Fig. 6-9A): (1) The aortic orifice, the ascending and the trans-

may bridge the right atrium and ventricle may be normal, or accessory, multiple bicuspid ventricular chamber. The conduction system elastosis is often present in the proximal right. The pulmonary artery is usually small. The ventricle may be normal or hypertrophied. or normal in thickness. The left atrium and of the right ventricle may be hypertrophied of the right ventricle is dilated. The distal part hypertrophied and dilated. The proximal part patent foramen ovale. The right atrium is less commonly, stenosis. There is usually a functionally or the seat of an insufficiency, or, may be small or large and may be normal not be attached. The new "tricuspid orifice" tached at all. The septal leaflet may or may

Fig. 6-8 Tricuspid atresia

atrium, B. Right ventricle, C. Tricuspid atresia, D. atrial septal defect, E. right atrial and proximal right ventricular chamber, F. proximal chamber, G. conus (C. D. From M. Lev, Autopsy Diagnosis of Congenitally Malformed Hearts, Charles C Thomas, 1953)

creased pulmonary flow. It appears that the total ventricular mass is greater than normal, but this is not certain.

**Complete Transposition with Single Ventricle and Diminutive Outlet Chamber.** In this anomaly (Taussig, 1938; Megeved et al.), the mitral and tricuspid orifices enter a single common chamber (Fig 6-7C). This chamber communicates by a variously sized opening with a smaller chamber situated humplike over the anterior wall of the main chamber. The aorta emerges from the diminutive chamber, while the pulmonary artery emerges from the main chamber. Either vessel may be large or small, dependent upon size of the communication between the two chambers. The main ventricular chamber is a common ventricle, while the recess is produced by the crista supraventricularis forming a pseudoseptum.

**PATHOGENESIS OF THE COMPLEX** The basic anomaly may again be considered to be the position of the arterial trunks. Since the pulmonary artery is usually related to the large chamber, there is increased pulmonary flow.

**Complete Transposition with Mitral and Tricuspid Atresia.** This will be considered under mitral and tricuspid atresia.

**Corrected Transposition.** In this anomaly (Cardell), the arterial trunks emerge in a completely transposed position, yet the aorta receives aerated blood. This is achieved by inversion of the atria, or the atria and ventricles, or the ventriculobulbar loop. There may be an associated ventricular septal defect.

**PATHOGENESIS OF THE COMPLEX** Should there be no other associated anomalies, the heart may function normally. Because of abnormalities in the AV node and bundle, there may be AV block.

## TRICUSPID ATRESIA AND STENOSIS COMPLEXES

In these complexes, the tricuspid orifice is either absent or smaller than usual. Always associated with these are (1) a diminutive right ventricle, (2) an atrial septal defect, and (3) left and right atrial and left ventricular hypertrophy.

**Tricuspid Atresia or Stenosis without Transposition.** In the complexes without transposition of the arterial trunks (Edwards and Burchell; Gasul et al.; Lev, 1953), there are three basic types (Fig. 6-8A, B). (1) There is

a ventricular septal defect of varying size. If the defect is small, there is a small but functioning right ventricle with a small pulmonary artery. If large, then the pulmonary artery may be normal in size or even larger than the aorta. (2) There is either pulmonary or infundibular atresia and an absence of the ventricular septal defect and, hence, a non-functioning minute right ventricle. (3) There is tricuspid stenosis with pulmonary stenosis or atresia. Here the right ventricle is small in size, with a very thick wall and fibroelastosis of the endocardium. The ventricular septum is intact.

**PATHOGENESIS OF THE COMPLEX** The basic anomaly is the tricuspid atresia (see Chap 1). The foramen ovale remains open because of pressure in the right atrium. This opening is usually smaller than the tricuspid orifice, and hence there is a physiologic stenosis at the foramen ovale. Thus the right atrium presents a pressure hypertrophy. The left atrium and left ventricle receive the combined pulmonary and right atrial flow and, hence, present a volume hypertrophy. If there is a ventricular septal defect, then the left ventricle contracts against decreased peripheral resistance and, hence, is less hypertrophied. The right ventricle is, in general, small because of decreased flow. It may be normal in size, however, if there is a large ventricular septal defect. If there is tricuspid stenosis and pulmonary stenosis or atresia, the pathogenesis of the thick right ventricular wall and of the fibroelastosis is obscure.

**Tricuspid Stenosis and Atresia with Transposition of the Arterial Trunks.** In this group of complexes, there is complete transposition of the arterial trunks, which alters the morphology of the heart. Depending upon the size of the ventricular septal defect, the aorta may be large or small. Aortic or pulmonary atresia may occur.

**Elstein's Complex.** In this complex (Gotzsche and Falkholt; Brown et al.; Lev et al.), the tricuspid valve is displaced downward into the right ventricle and divides this chamber into a thin-walled proximal and a thicker-walled distal segment (Fig 6-8C, D). The position of the tricuspid valve is often at the line of junction of the sinus and conus. The anterolateral leaflet is partly attached to the annulus, while the posterior is not at-

TABLE 11-2. ETIOLOGY OF BUNDLE BRANCH BLOCK

| Type of BBB | Type of patient             | Cause of block  |

in the study of congenital heart disease, having important implications from the standpoint of both electrogenesis and differential diagnosis

In older patients, the appearance of right bundle branch block is usually due to coronary arteriosclerosis. In such instances, the block is usually complete, with left axis deviation and counterclockwise rotation. Lead I usually exhibits a qRs configuration (with a slurred S wave), and lead III shows an rSr' configuration.

Another common cause of right bundle branch block is *cor pulmonale*, in both its acute and chronic forms. Under these circumstances, AQRS is usually deviated to the right, with clockwise rotation and signs of right atrial enlargement, in addition to other classical signs of these conditions

Bundle branch blocks of any variety may appear in several forms of myocarditis, in thyrotoxicosis, in myocardial disease of unknown etiology, in myocardial tumors, cysts, gummas, trauma, etc. In addition, they may be caused by the *toxic effects* of several drugs, such as digitalis, quinidine, and Pronestyl, and

also may appear in certain endogenous intoxications, such as hyperkalemia due to acute or chronic renal insufficiency (Schlesinger and Benchimol, 1956).

### CLINICAL FINDINGS

There are no symptoms that are diagnostic of bundle branch blocks, the clinical manifestations that may occur are due either to the etiologic factor involved or to an unrelated clinical syndrome.

There are, however, certain signs which may result from ventricular asynchronism and, therefore, are directly related to the bundle branch block. These signs are (King, 1928) a double cardiac impulse, a muffled and prolonged 1st sound, and a split 2d sound. A presystolic gallop rhythm and a midystolic apical murmur, if present, are not related to the block.

Under special circumstances, the physical signs may suggest the presence of bundle branch block. The most important clinical finding is a distinct and wide splitting of the 2d heart sound (Cossio et al., 1940).

Clinically, left bundle branch block may be suggested if there is a presystolic gallop rhythm without heart failure and a split 2d heart sound with a late aortic component, so that the reduplication is accentuated by expiration. In right bundle branch block, there is a more distinct splitting of the 2d sound with a marked delay in the pulmonic component, which is highly suggestive. Left bundle branch block indicates in most patients a diffuse type of heart disease, whereas right bundle branch block is not necessarily a sign of serious cardiac involvement.

### PROGNOSIS

Bundle branch blocks were formerly considered to have an ominous prognostic significance, it is now believed that it is not the conduction disturbance itself but the etiologic factor involved, especially the nature and degree of the myocardial damage, which dictates the prognosis in each case (Schreenivas et al.)

Although it is not rare to find bundle branch block as the sole manifestation of cardiac disease (in certain cases with a long survival), these conduction defects usually indicate an extensive myocardial damage, which in most patients is a result of arteriosclerotic heart disease.

# The Wolff-Parkinson-White syndrome and other forms of preexcitation

EUGENE LEPECHKIN

L. Wolff, J. Parkinson, and P. D. White described (1930) a syndrome which usually appeared in young persons with occasional paroxysmal tachycardia (but otherwise normal hearts) and was characterized by a *short P-R interval and a wide QRS complex* resembling bundle branch block. Many of these persons showed on other occasions normal QRS complexes with normal P-R intervals, the P-J interval to the S-T junction usually remaining the same length as in the aberrant complexes. Ohnell, who studied the syndrome extensively (1940), showed that it was caused by *premature excitation* of a part of the ventricle by the atrium, and introduced the term *preexcitation* to designate this as well as other less characteristic electrocardiographic patterns. In the typical pattern, the wide premature component of the QRS complex is of relatively low voltage and shows a distinct kink with the slender terminal portion of the QRS complex, which corresponds to normal activation of the ventricles through the AV node and is nearly identical in the normal and the aberrant complexes. In the vectorcardiogram, this premature portion usually moves two to three times more slowly than the rest of the QRS loop (Grishman and Jaffe, Wolff and Richman). The slow premature portion has been called by Segers et al (1947) *the delta wave*, as it resembles the Greek letter  $\Delta$  in configuration (Figs. 11-39, 11-40).

In some cases, not only the initial, premature portion of the QRS complex but also its terminal portion is wide and slurred, and the form of the

QRS complex is identical with that of bundle branch block. This pattern appears when normal activation through the AV node is delayed or absent, and the ventricles are activated exclusively in the premature manner, directly from the atrium. In such cases, the P-R interval of the normally conducted complexes is usually prolonged (Blum) or the AV bundle is completely interrupted (Mahaim, Scherf et al.). This pattern was designated as *type F* by Ohnell, but in order to avoid confusion with the grouping according to the direction of the delta wave, it will here be called *complete preexcitation*. In other cases, the premature component of the QRS complex is of very short duration and may be hard to distinguish from a normal slurred onset of the R wave, the duration of the QRS complex in these cases is accordingly not prolonged beyond the upper normal limits (Fig. 11-41). This pattern results when the normal conduction through the AV node is especially rapid, and only a small section of the ventricles can be excited directly from the atria before the rest of the ventricular mass is excited through the normal conducting system. It is usually seen in persons with normally short P-R intervals, such as children or young women. Relatives of persons with this pattern also tend to show a short P-R interval (Koch). This pattern has been designated as *type A* by Ohnell but will be called here *rudimentary preexcitation*, to avoid confusion. A third atypical pattern, designated as *type E* by Ohnell, shows the usual slurred configuration of the QRS complex but a *long or normal P-R interval*, and is due to a delay in both the normal and the premature excitation of the ventricle, the P-R interval of the normally conducted beats is always prolonged (Mahaim, Koch,

Fig. 11-36(3). Complete right bundle branch with left axis deviation ( $\sim 100^\circ$ ). The VCG in the horizontal plane shows a clockwise rotation of the QRS loop with its major portion oriented to the right and anteriorly. Note slight counterclockwise rotation in the apical portion of the loop. Conduction delay is present in the afferent portion of the loop. The VCG is diagnostic of right bundle branch block and right ventricular hypertrophy. Note that the initial portion of the efferent loop is directed leftward and slightly posteriorly, suggesting an associated left ventricular hypertrophy, particularly in the presence of marked left axis deviation.

TABLE 11-3 BUNDLE BRANCH BLOCK IN CONGENITAL HEART DISEASE

| Type of BBH         | Cyanotic          | Noncyanotic   |
|---------------------|-------------------|---|
| Right               |                   |   |

Fig. 11-39 A Electrocardiogram of a 12-year-old girl during an attack of paroxysmal tachycardia. The T waves follow the QRS complex and are biphasic, but mainly upright in leads I to III. The QRS complexes are narrow, the alteration in amplitude of the R wave is common in all supraventricular tachycardias with very high ventricular rates. B. After termination of the attack, sinus rhythm with type B preexcitation is present. C. After medication with quinidine, preexcitation disappears. The fusion of the T wave with the U wave is part of the quinidine effect.

Right bundle branch block is usually considered to have a much less severe prognosis than left bundle branch block. Although this is true in most instances, one must consider each case from the clinical standpoint and not base the prognosis only on the type of bundle branch block.

Several investigators have attempted to determine the average survival time of patients with bundle branch block; some of them have found it to be relatively short. This would seem to indicate an unfavorable prognostic significance of these conduction disturbances. However, more recent statistical studies not only have shown much longer survival periods, but also have pointed out how difficult it would be to estimate how long patients can live with bundle branch block, because it is often impos-

sible to determine the duration of the block prior to its recognition.

### TREATMENT

There is no treatment of bundle branch block as such. Therapy must be directed toward the etiologic factors involved, when possible. Although there is no formal contraindication to the administration of *digitalis* in the presence of bundle branch block, if the conduction defect results from toxic effect of the drug, it is imperative to withdraw the medication, at least temporarily. *Quinidine* should be administered most carefully to these patients, under electrocardiographic control; administration should be stopped as soon as there is a further widening of the QRS complex or following the appearance of other types of conduction defect.

### INTRAVENTRICULAR BLOCK

Under this designation, a series of intraventricular conduction disturbances has been described, in which the main branches of the bundle of His are not involved. The delay in activation occurs in the more distal segments of the conduction system or in restricted areas of the myocardium in the free ventricular walls. According to Segers, the absence of anatomic lesions of the branches of the bundle of His in certain cases exhibiting electrocardiographic changes which closely resemble those of bundle branch block suggests the possibility of a *focal block* with conduction delay in limited zones of the ventricular myocardium. Because certain cases in which the EKG was characteristic of bundle branch block did not reveal, by electrokymographic studies, a delay in the onset of homolateral ventricular ejection, although a prolongation of the ejection period was observed, Segers suggests that the delay in the spread of the activation wave occurs in the lateral walls of the ventricle, representing what he has called *parietal block*. Other authors had previously described cases in which a conduction delay occurred in extensive areas of the ventricular walls at the distal ramifications of the conduction system. Oppenheimer and Rothschild described cases with wide QRS complexes and low voltage under the designation of *arborization block*.

According to Grant, parietal block is due to disseminated lesions involving the anterior division of the left branch of the bundle of His;

in these cases, the QRS complexes are not necessarily widened, the beginning of ventricular activation is normal, and the conduction delay occurs only in the lateral walls. This results in marked left axis deviation in view of the orientation of the terminal vectors, which are directed leftward and superiorly.

An electrocardiographic pattern showing deep S waves in leads II and III, exceeding the amplitude of the R waves, in the absence of S waves in lead I, has recently been described by Davies and Evans as due to a conduction disturbance in the peripheral branches of the left branch of the bundle of His. They attribute these lesions usually to ischemic changes and believe that the diagnosis of myocardial infarction is highly probable in patients with this type of EKG and with symptoms of cardiac pain.

When the focal lesion is more extensive and is localized in the subendocardial areas of the high anterolateral wall of the left ventricle, in addition to the involvement of the anterior division of the left branch of the bundle of His, resulting in left axis deviation, the initial portions of the QRS complex are also affected, this has been called *peri-infarction block*, and is characterized by a wide Q wave which is associated with left axis deviation [Fig 11-36(4)].

The main electrocardiographic feature of peri-infarction block is the widening of the angle between the initial and terminal 0.04 sec

Fig. 11-40. The limb lead electrocardiograms of Fig. 11-39B are superimposed on corresponding leads of the same patient taken several weeks later when no preexcitation or quinidine effects were present. It can be seen that the increase in the positive area of the QRS complex (horizontal shading) is equal to the decrease in the positive area of the T wave and S-T segment (vertical shading).

Glushien and Goldblum, Pick and Katz). This pattern will be called *delayed preexcitation*.

According to the direction of the premature component of the QRS complex in the precordial leads, Rosenbaum, Hecht, Wilson, and Johnston distinguished two groups of cases. In "group B" this component is upright in the unipolar precordial leads  $V_2$  through  $V_6$  but inverted in  $V_1$  (and sometimes also in  $V_2$ ), the right, lower, and posterior portions of the thorax, and usually also aVF; in the frontal plane, this component shows usually left axis deviation but sometimes a normal axis. In this group, the highest negative voltage of this component was found in leads from the right atrium near the tricuspid valve and in the lower esophagus, while leads from the cavity of the right ventricle and the coronary vein showed a positive premature component (Grishman et al., Giraud et al.; Hecht et al., 1957). This indicates that the prematurely excited ventricular muscle is on the posterolateral epicardial surface of the right ventricle, near the AV groove. In group A, the premature component of the QRS complex is negative on the back but positive in leads  $V_1$  through  $V_6$  and usually also in aVF, so that its axis in the frontal plane is usually normal or deviated to the right, and only occasionally deviated to the left. In intracardiac leads, some cases of this group showed the same findings as in group B, and the difference in the configuration of leads  $V_1$  to  $V_2$  in these cases was therefore attributed to a different position of the heart (Grishman et al.). However, in cases of this group

Fig. 11-41. Electrocardiogram of a 22-year-old woman with rudimentary preexcitation of type A, who complained of occasional rapid heart action. No electrocardiogram could be taken during the attack. The lower strip shows "concertina effect," leading to pseudonormalization during the pressor phase of the Valsalva maneuver and to increased preexcitation during the postpressor phase. One ventricular extrasystole appears at the end of the tracing.

Fig 11-36(4). Focal perinfarction block in a 67-year old male. The ECG displays wide Q waves in leads I and VL (high lateral infarction) associated with left axis deviation ( $-85^{\circ}$ ) and a QRS duration of 0.12 sec. The VCG reveals a counterclockwise rotation in the horizontal plane, as well as a conduction delay in the terminal portions of the loop in the three planes.

which showed an isoelectric or negative premature component in leads I and V, this component was positive in the right atrium and ventricle, but deeply negative in the coronary vein, which is in contact with the posterior aspect of the left ventricle near the AV groove (Giraud et al.). It was, therefore, concluded that this is the site of the prematurely activated portion of the ventricle. Such cases constitute less than 20 per cent of all persons with the Wolff-Parkinson-White syndrome. In both groups, the subepicardial location of the prematurely excited section accounts for the low voltage and long duration of the premature component of the QRS complex, since the rapidly conducting Purkinje fibers do not penetrate to the epicardium.

Holzmann and Scherf and, independently, Wood and coworkers suggested that the premature excitation of the ventricle by the atria could take place through an accessory bundle similar to that first described by Kent (1933). This bundle consists of nonspecialized muscle and can, therefore, be expected to conduct excitation more rapidly than the specialized thin muscle fibers of the AV node, whose function is to delay excitation of the ventricle. A subepicardial accessory muscle bundle connecting the posterolateral aspects of the right ventricle and atrium was actually found in two cases with the preexcitation syndrome (Levine and Burge, Lev et al.), and three similar subendocardial bundles were found in another case (Wood et al.). In still another case, the connection was between the atrial and ventricular septa on the right side (Segers et al., 1947). All these cases belonged to group B. A subepicardial connection between the left atrium and ventricle was found in two cases (Olmsted, Mahaim), and an additional case showed both a right-sided and a left-sided connection (Kimball and Burch). All these cases belonged to group A and showed a negative premature component in lead I; the electrocardiographic pattern accordingly is in keeping with the anatomic location of the aberrant pathway. On the other hand, the incidence of this pathway in routine autopsies is no greater than that of preexcitation (Lev et al.).

However, in several persons who had shown preexcitation, no accessory bundle could be found despite careful histologic study (Soderstrom, Hecht et al., 1957). In these cases, another explanation must be sought. Holzmann

and Scherf suggested that preexcitation can be due to stimulation of an acquired irritable ventricular center by the stretching effect of atrial contraction; such a center could also be set off by the action potential of atrial fibers (Segers et al., 1947). As these effects would be greatest near the AV border, especially if there is intimate contact between atrial and ventricular muscle fibers, as in the cases of Soderstrom and Langendorf et al., the localization of the premature component would be in keeping also with this hypothesis. Stable preexcitation complexes were often seen to appear during cardiac catheterization, Giraud et al. found this in more than one-third of all catheterizations. Friesmetal et al. (1952) could elicit such complexes most commonly by applying pressure, or a subthreshold electric current, to the inner surface of the ventricles through the catheter. In these cases, atrial contraction was probably transmitted mechanically through the catheter or the stimulating electrode. Preexcitation also could be elicited by injection of aconitine or epinephrine into the ventricular septum near the AV border (Frau and Maggi), and may also appear after intravenous injection of strophanthine (Vakil) or epinephrine (Fig. 11-42). All these procedures increase ventricular excitability. In all these cases, the complexes with short P-R interval and wide QRS complex usually showed transitions to ventricular parasystolic rhythms or coupled extrasystoles showing no relation to the P waves. It is very difficult to decide in a given case whether true coupling of the ventricular complexes to the P waves exists or whether the relation between the wide QRS complex and the P wave is a fortuitous one. Furthermore, there are many factors which may cause synchronization of P waves to the preceding QRS complexes (Rosenbaum and Lipeschkin), and the designation of preexcitation cannot be applied to them. True preexcitation becomes probable if the short P-R interval remains completely constant during a series of beats (Pirk and Katz), but it can be proved definitely only if this interval remains constant even in the presence of spontaneous or induced variations of the P-wave rhythm. A mechanical coupling can be expected to produce a rather loose synchronization, since the instant when a given tension is exerted on the ventricle would vary with the stroke volume,

of the QRS complex. With rare exceptions, in the presence of left axis deviation, when this angle exceeds  $100^\circ$  the EKG is diagnostic of anterolateral peri-infarction block. This type of conduction disturbance was initially described in 1950 by First and coworkers, who interpreted it as being due to the involvement of extensive areas of the subendocardial portions of the ventricles and of the Purkinje network. Under these circumstances, the impulse spreads through the noninvolved myocardium

around the infarcted area, and its conduction is delayed at this point.

Finally, a type of *diffuse intracardiac block* has been described that resembles left bundle branch block, with Q waves in left precordial leads.

These cases are apparently due to a diffuse conduction disturbance through the ventricular wall, resulting from left ventricular hypertrophy, diffuse myocardial fibrosis, quinidine toxicity, or hyperpotassemia.

## GRAPHIC DATA IN BUNDLE BRANCH BLOCK

### PHONOCARDIOGRAM

The 1st sound is *prolonged* and lasts more than 0.16 sec. It is frequently of low amplitude. *Splitting of this sound* has been described by several authors. However, this observation is not confirmed by "stethoscopic" tracings and should be attributed to either inadequate or different techniques. Ventricular asynchronism results in the delay of the contraction of one ventricle over that of the other of about 0.04 to 0.05 sec. This interval is too short for causing a splitting of the central phase of the 1st sound, which lasts from 0.06 to 0.08 sec. However, it causes prolongation of

the sound in both right and left bundle branch block. If *left ventricular hypertrophy* and *intraventricular block* add their effects to that of *left bundle branch block*, the delay between the contractions of the two ventricles may reach 0.06 sec or more. Then, closing of the mitral valve (first valvular event of the left heart) takes place at the time of opening of the pulmonic valve (second valvular event of the right heart) because the normal isometric tension period (about 0.05 sec) lasts as long as the pathologic interval between the contractions of the two ventricles. The phonocardiogram then reveals *three groups of vibrations*, the first is due to tricuspid closure; the second,

Fig. 11-37. A. Simultaneous phonocardiograms over the aortic (Ao) and pulmonic (Pulm. A) areas, compared with carotid tracing and unipolar ECG chest leads. Time, 0.1 sec. The second component of the 2d sound is visible only in the pulmonic tracing and does not coincide with the incisura of the carotid pulse. Diagnosis: right ventricular delay due to right bundle branch block. B. Simultaneous phonocardiograms over the aortic (Ao) and pulmonic (Pulm. A) areas, compared with carotid tracing and unipolar ECG chest leads. Time, 0.1 sec. The second component of the 2d sound is visible over both areas of the base and coincides with the incisura of the carotid pulse. The aortic 1st sound occurs later than the pulmonic 1st sound. Diagnosis: left ventricular delay due to left bundle branch block.

heart position, etc. An electrical coupling, on the other hand, would be much more constant, since the shape of the P waves and the sequence of activation of atrial muscle near the AV border show only insignificant variations.

A third hypothesis, advanced by Prinzmetal and coworkers (1952), is that the premature activation of the ventricle is due to accelerated conduction in part of the fibers of the AV node. Experiments considered as proof of this hypothesis are open to criticism (Sodi Pallares, 1956, Hecht et al., 1957). Furthermore, it would not explain the slow ascent of the premature component of the QRS complex, since premature activation of the rapidly conducting specific system would cause a rapid initial component.

The incidence of the typical Wolff-Parkinson-White pattern is 0.02 to 0.04 per cent in children (Landtman; Vacheron), 0.07 to 0.1 per cent in apparently normal adults and in ambulatory patients (Hecht et al., 1957), and 0.16 per cent in hospitalized patients. This increased incidence with age and severity of disease, together with its appearance in infections or rheumatic heart disease, could be considered as favoring an acquired genesis of the syndrome. The explanation of Pick and Katz, that any acquired factors which impair normal AV conduction would facilitate congenital aberrant conduction, does not seem plausible, since aberrant conduction takes place before normal conduction. However, since conduction in aberrant anatomic pathways may be present only occasionally (Lyle), the increased inci-

dence of aberrant complexes under abnormal conditions may be simply the result of the electrocardiograms being taken more often and in longer strips. On the other hand, the smaller incidence in children may be due to the short normal P-R interval, which may mask all or part of the aberrant conduction.

The fact that preexcitation was repeatedly found in two or more members of the same family (Ohnell; Koch; Hecht et al., 1957) is strongly in favor of a congenital origin of this anomaly, as are the occurrence of other congenital anomalies and the high incidence (0.7 per cent) of preexcitation in persons with congenital heart disease (Hecht et al., 1957) and the fact that preexcitation is twice as common in males as in females in all age groups (Vacheron; Lown et al.).

Increase of the heart rate, whether spontaneous or due to exercise, the Valsalva maneuver (Fig. 11-41), standing up, fever, atropine, amyl nitrite, or Banthine, usually causes the premature component of the QRS complex to become shorter and the QRS complex more normal, this is because of acceleration of normal AV conduction, which causes more of the ventricle to be activated in a normal manner. Occasionally, the premature component may disappear completely, this "pseudonormalization" can be distinguished from true normalization by the fact that the P-R interval remains short. True normalization may occur also, in this case the P-R interval becomes longer. This can be explained by assuming either that

Fig. 11-42. Alternating preexcitation appearing in a cat after injection of myocardial sympathin. B The premature component of the QRS complex appears progressively later and disappears at the end of the tracing

to pulmonic opening plus mitral closure; the third, to aortic opening. A similar phenomenon, with delay of right ventricular events, occurs when right intraventricular block and right ventricular hypertrophy add their effects to that of right bundle branch block.

It is probable that a new study by means of "selective phonocardiography," with its scanning of adjacent bands of sounds, will reveal different data, possibly including a "splitting" of the 1st sound. (The quotes are necessary because the 1st sound already presents a "physiologic" splitting when recorded in normal subjects in the band 240 to 480 cps.)

The 2d sound, being shorter, is constantly split in bundle branch block. In the case of right bundle branch block, as the pulmonic component normally follows the aortic component of the 2d sound by 0.02 sec, the 2d sound is widely split, and there is an interval of about 0.05 to 0.07 sec between the aortic and the subsequent pulmonic component (Fig. 11-37A). In the case of left bundle branch block, the opposite occurs. If there is only a slight delay of the aortic component, it will fall at the time of the pulmonic component (no splitting of the 2d sound). If, on the other hand, there is a severe delay, then the aortic component will follow the pulmonic component by 0.02 to 0.04 (paradoxical splitting of the 2d sound, Leatham) (Fig. 11-37B).

### CAROTID TRACING, JUGULAR TRACING

The delay between the beginning of the 1st sound and the rise of the carotid pulse (usually about 0.05 sec) is increased and lasts from 0.07 to 0.08 sec in left bundle branch block. The incisura of the carotid pulse coincides in normal subjects with the main vibration of the 2d sound (aortic component). In left bundle branch block, it coincides with the 2d phase of the split 2d sound (aortic component) (Fig. 11-37B). The rise of the carotid pulse has a normal relationship to the beginning of the 1st sound in right bundle branch block. The incisura has a normal relationship to the 1st phase of the split 2d sound (aortic component) in this type of block (Fig. 11-37A) while the pulmonic component occurs later.

In right bundle branch block, the study of the jugular tracing is of importance. The peak of the V wave is markedly delayed and occurs

0.08 to 0.14 sec after the end of the 2d sound (or after the 2d phase of the 2d sound, if this is split). In other words, the V wave, which usually occurs 0.08 to 0.14 sec after the 2d sound, has the same relationship to the pulmonic component (2d phase) of this sound, when it is split.

### ELECTROKYMোগRAM

This method may be applied to the study of pulmonic or aortic pulsations. In most cases, it may be applied to the study not only of left ventricular but also of right ventricular contraction. Moreover, right atrial tracing is so deeply influenced by right ventricular contraction that the phases of right ventricular dynamics may be studied even by recording a right atrial border tracing. The best technique is that of recording simultaneously a high left ventricular tracing and a pulmonic tracing, then, a right ventricular (or right atrial) tracing with an aortic tracing.<sup>2</sup> The study may be completed by the simultaneous observation of the anterior (right ventricle) and posterior (left ventricle) surfaces of the heart. It should be kept in mind that while direct comparison of the two ventricles has a decisive importance, comparison of one ventricle with one pulse (or of the aortic and pulmonic pulses) is less significant on account of possible interaction of peripheral factors which may accelerate or delay the valvular events.

Normal time relationships between the two ventricles and the two large vessels were studied by the author and his coworkers (1948) and by Samet and coworkers (1950b). In spite of slight individual and phasic variations, it can be assumed that the two ventricles and the two large arteries present pulsations which succeed each other within 0.02 sec. The most common is the precession of the pulmonic pulse by 0.020 sec (Part 4, Chap. 8).

In about 30 per cent of the cases of left bundle branch block, left ventricular contraction and the aortic pulse are delayed over the

<sup>2</sup> If one has only a pickup unit, the study should be made in the following way: (1) aortic electrokymogram (EKy) plus sound tracings, (2) pulmonic EKy plus sound tracings, (3) left ventricular EKy plus sound tracings, (4) right ventricular (or right atrial) EKy plus carotid and sound tracings, (5) comparison of the four tracings using the sound tracing as timer. It should be noted that use of the carotid tracing as timer is confusing in these cases of bundle branch block because the carotid pulse is necessarily delayed in left bundle branch block.

at high heart rates conduction in an anatomic aberrant pathway does not take place because of fatigue, or that the mechanical effect of atrial contraction is smaller because of the decreased stroke volume. On the other hand, decrease of heart rate, such as that caused by carotid sinus pressure, the late phase of the Valsalva maneuver (Fig 11-11), or medication with *Prostigmine*, *Mecholyl*, or *digitalis*, usually increases the duration and magnitude of the premature component of the QRS complex because of slowing of normal AV conduction. During this effect, the P-R interval remains short but the P-J interval increases. In many cases, the above factors led to the appearance of preexcitation complexes.

The remarkable constancy of the P-R interval in preexcitation may be due to the fact that an aberrant pathway, consisting of non-differentiated ventricular muscle, would not be influenced by the vagal effects which cause prolongation of the normal AV conduction together with bradycardia. It would also be in keeping with an electrical, but not with a mechanical, excitation of a ventricular irritable focus by the atrium, as mentioned above. The only factors which influence the P-R interval seem to be *quinidine* and *procaine amide*, which usually cause the premature component of the QRS complex to appear progressively later, to become smaller, and finally to disappear completely (Blinder et al., Zapata Dias et al.). In these cases, the P-R interval becomes longer while the P-J interval is usually unchanged. In some cases, normalization takes place abruptly. The action of these drugs would be in keeping with a slowing of conduction in an accessory bundle, but not in the AV node, since they have a greater effect on nonspecific ventricular muscle. It would also be in keeping with an ectopic ventricular focus stimulated by atrial activity, as the same drugs decrease ventricular excitability, a gradual and considerable prolongation of the P-R interval would be more difficult to explain on this basis, since the moment of excitation would then occur considerably after the maximal electrical and mechanical effects of atrial excitation. The occurrence of delayed preexcitation would also be difficult to explain on this basis. Finally, the occurrence in some cases of preexcitation of Wenckebach's periods, i.e., of progressive prolongation of the P-R interval leading to

complete AV block followed by shortening of the P-R interval (Levine and Burge, Scherf et al., 1953; Hecht et al., 1957), could not be explained on any other basis except that of an aberrant AV bundle.

When AV nodal beats occur in preexcitation, either spontaneously or during the initial, bradycardiac action of atropine, during carotid sinus pressure, or after injection of *Neosynephrine* (Ohnell), they always show a normal QRS complex if the P wave follows the QRS complex. In these cases, the ventricle is excited entirely through normal pathways before preexcitation can take place. Occasionally, when the P wave precedes the QRS complex slightly, a delta wave may appear, but it is always shorter than in the usual preexcitation complexes. In a few cases, this wave was present even when no P wave preceded the QRS complex; in these cases the rhythm could have originated in the accessory bundle, or this bundle could have originated in the AV node itself.

*Paroxysmal tachycardia* was found in about 70 per cent of all cases showing the Wolff-Parkinson-White pattern, in children, this percentage was 93 per cent (Vacheron). On the other hand, it constitutes about 11 per cent of the cases of paroxysmal tachycardia, in children this percentage was 12 per cent (Nadas et al.). The higher incidence in children can be explained by the fact that electrocardiograms in children are seldom taken unless there is a conspicuous alteration of rate or an arrhythmia. In most cases the QRS complexes were regular and narrow, and were followed after about 0.10 sec by inverted or diphasic P waves, the premature portion of the QRS complex was absent. The tachycardia was therefore designated as nodal, but, in contrast to typical nodal tachycardia, the P waves were often upright in lead I. The appearance of this type of tachycardia can be explained by means of a special form of "circus movement" from the ventricle to the atrium through an accessory AV bundle, and back to the ventricle through the normal AV conduction system. It could not be explained at all on the basis of an excitable ventricular center, for this would cause a ventricular tachycardia.

The beginning and end of the paroxysmal tachycardia was studied repeatedly only in a few cases. In two of them (Juncadella Ferrer,

Fig. 11-38. Scheme of the electrokymograms of the aortic and pulmonary arches in right (above) and left (below) bundle branch blocks with ventricular asynchronism. (From Luisada, *Heart Beat* Hoeber, 1953.)

right ventricular and the pulmonic pulse by about 0.03 to 0.05 sec (Fig 11-38). If there is hypertrophy or intraventricular block of the

left side, the delay is greater. Hypertension of the greater circulation increases the delay revealed by the rise of the pulse, decreases that revealed by the incisura.

In about 30 per cent of the cases of right bundle branch block, the right ventricular contraction and the pulmonic pulse are delayed over the left ventricular and the aortic pulse by about 0.03 to 0.05 sec (Fig. 11-38). If there is hypertrophy of the right ventricle or intraventricular block of the right side, the delay is greater. Hypertension of the lesser circulation increases the delay revealed by the rise of the pulse, decreases that revealed by the incisura. Systemic hypertension may partly neutralize the effect of right bundle branch block, so that the delay is less apparent.

In both types of block, a prolongation of the phase of isometric relaxation was observed. A large percentage of cases of bundle branch block, whatever the side, seem to present a bilateral delay of contraction upon EKy studies. Phonocardiographic studies reveal a much larger percentage of asynchronism than EKy studies.

Tommaselli), frequent atrial extrasystoles were present; if they appeared late, they were followed by QRS complexes with delta waves, but if they appeared early enough, they were followed by a narrow QRS complex, followed in turn by a diphasic P wave and an access of paroxysmal tachycardia. Still earlier extrasystoles were followed by narrow QRS complexes only, or were blocked. Apparently circus movement becomes possible only if an atrial extrasystole appears early enough to find the accessory bundle still refractory but late enough for it to recover by the time excitation is conducted to the ventricle. The attack was terminated either by a diphasic P wave after progressive lengthening of the P-R interval (block in the AV node) or suddenly by a QRS complex (block in the accessory bundle). In other cases (Rosenbaum et al., 1945; Katz and Pick), the attacks were initiated in the same way by lower nodal extrasystoles, with the first few complexes of the tachycardia showing a wide QRS complex without a slow initial component, because of aberrant intraventricular conduction. In the case of Lyle, the atrial extrasystoles elicited runs of tachycardia with wide QRS complexes showing delta waves, in this case, the normal conducting system could have been still refractory while excitation was conducted down the accessory bundle, but became conducting by the time excitation reached it retrogradely from the ventricle. These cases show that a premature stimulus is necessary to establish circus movement and explain the numerous observations in which no paroxysmal tachycardia appeared until the occurrence of some acute infection, which could have precipitated extrasystoles responsible for circus movement. In most cases the tachycardia can be interrupted by digitalis, while in some, quinidine is more effective. This can be explained by assuming that circus movement can be terminated either by blocking the AV node with digitalis or by blocking the accessory bundle with quinidine.

In a minority of the cases with preexcitation, atrial fibrillation is registered during the accesses of paroxysmal tachycardia, and a few cases show atrial flutter (Pick and Katz). The case of Tommaselli shows clearly how the typical "nodal" type of tachycardia attributed to circus movement through the aberrant bundle can be transformed into atrial flutter and finally

into atrial fibrillation; any rapid stimulation of the atria can lead to the same sequence. These arrhythmias can accordingly be explained on the basis of an accessory bundle, but not on that of an excitable ventricular center. When atrial fibrillation is present, runs of normal QRS complexes usually alternate with groups of complexes showing very wide delta waves (complete preexcitation). These groups can be explained by assuming that when excitation takes place over the accessory bundle, the normal AV bundle is excited later and retrogradely, and therefore recovers its conductivity later than the accessory bundle, so that the constantly circulating fibrillation waves are likely to enter the accessory bundle again (Pick and Katz). As in atrial fibrillation, co-ordinated atrial contractions are absent, the appearance of preexcitation in these cases cannot be explained by mechanical effects of atrial contraction, while stimulation by electrical effects would still be possible. One peculiarity of atrial fibrillation with preexcitation is that the ventricular rate is usually very rapid, and the usual slowing effect of digitalis medication on this rate is absent (Katz and Pick, Giraud et al.). This can be explained by the fact that this slowing effect is due to a blocking effect of digitalis on the AV node; the drug would not have effect on a muscular accessory pathway. Quinidine, which blocks also the accessory pathway, must be combined with digitalis in such cases.

In many cases of preexcitation, the paroxysmal tachycardia was interpreted as being of ventricular origin, but closer scrutiny of the tracings always made it seem probable that in reality atrial fibrillation with complete preexcitation was present (Langendorf et al.; Giraud et al.) True ventricular tachycardia becomes probable only in cases where ventricular extrasystoles of the same form had appeared previously (Frau and Maggi). In these cases, the explanation of the syndrome as due to an excitable ventricular center is more likely.

Occasionally the slope of the premature component of the QRS complex in preexcitation complexes may be so slight that this component can be mistaken for an ascending P-R segment; if this slope is less than 2.5 m/sec, the term "type B" was used by Ohnell, but we shall call this pattern *low-voltage preexcitation*. This type often results from superposition of a descending P-R segment

on the delta wave and usually becomes more typical with slowing of the heart rate, especially in the precordial leads. A much more common pattern shows a short P-R interval but an apparently normal QRS complex. It can represent preexcitation with a very steep and rapid delta wave, but this diagnosis can be made with certainty only if QRS complexes of different configuration and with a longer P-R interval can be observed to appear. In this type of "rapid preexcitation," designated as "type C" by Ohnell, the accessory bundle could terminate in the bundle of His. On the other hand, the pattern can correspond to accelerated conduction in the AV node. Lown et al found that the incidence of paroxysmal tachycardia in such cases was much less than in typical preexcitation (only 10 per cent), while the percentage of cases among females was much greater (70 per cent), most of them had signs of adrenal cortical excessivity. In some of these cases, the P-R interval became longer after digitalis administration but the QRS complex remained identical, and in these an accessory bundle could be definitely excluded.

The recognition of preexcitation is important, first of all because, although deaths due to paroxysmal tachycardia have been reported in this condition, its prognosis is much better than that of left bundle branch block with which it may be confused. The differentiation is easy in the presence of a typical delta wave, but complete preexcitation may look almost exactly like bundle branch block, especially if the P-R interval is borderline or atrial fibrillation is present. Usually, the initial slope of the QRS complex in right precordial leads is steeper in bundle branch block than in preexcitation, but sometimes a definite diagnosis can be made only by conversion to sinus rhythm or by application of agents which cause acceleration of AV conduction or true normalization. A Valsalva maneuver or subcutaneous injection of 1 mg atropine may cause the appearance of nodal escape beats with a normal QRS complex, accelerated AV conduction, or pseudo normalization. Slow intravenous injection of procaine amide at the rate of 200 mg/min up to 1 Gm caused normalization in 7 out of 9 cases without side effects (Zapata Diaz et al.).

Preexcitation complexes showing a negative delta wave in leads I or II or III may imitate the deep Q wave of myocardial infarction. On the other hand, positive delta waves may pre-

vent the deep Q waves of infarction from appearing, and old infarction can be recognized in such cases only after normalization. The changes of the R wave and S-T segment caused by infarction can also be masked by preexcitation, but in most cases, closer inspection allows their recognition. The secondary changes of the T wave and S-T segment in preexcitation are always opposite in direction

to those of the QRS complex (Fig 11-10). The total QRS complex (ventricular gradient) remains the same (Bercow et al.). Accordingly, if the S-T segment is depressed in a lead where the premature

complex is only slightly positive, these changes must be taken to be primary and to indicate additional myocardial damage. It must be emphasized, however, that the primary T-wave inversion may appear in preexcitation without myocardial infarction after accesses of paroxysmal tachycardia, especially if treated with quinidine, in these cases, the T-wave changes remain after normalization. Another source of error may appear in rudimentary preexcitation, where the change in the QRS area may not be sufficient to cause an abnormal configuration of the QRS complex but sufficient to cause depression of the S-T segment and a biphasic T wave, which can be erroneously interpreted as denoting myocardial damage.

In the presence of paroxysmal tachycardia, the recognition of preexcitation is important for treatment, since if circus movement through the accessory bundle is the cause of tachycardia, quinidine or procaine amide should be beneficial even if this appears to be "supraventricular." Quinidine will also prevent the appearance of single atrial extrasystoles, which are often instrumental in precipitating an attack. Recently Chlorpromazine has been found beneficial, alone or in conjunction with procaine amide, even where the latter alone was ineffectual (Graud et al.). The presence of upright P waves in lead I in "nodal tachycardia" or of the peculiar groups of wide QRS complexes in atrial fibrillation makes preexcitation probable, but it can be established only when delta waves can be identified in previous tracings or appear between attacks. It must be emphasized that after the tachycardia has

Fig. 11-38. Scheme of the electrokymograms of the aortic and pulmonary arches in right (above) and left (below) bundle branch blocks with ventricular asynchronism. (From Luisada, *Heart Beat*, Hoeber, 1953.)

right ventricular and the pulmonic pulse by about 0.03 to 0.05 sec (Fig. 11-38). If there is hypertrophy or intraventricular block of the

left side, the delay is greater. Hypertension of the greater circulation increases the delay revealed by the rise of the pulse, decreases that revealed by the incisura.

In about 30 per cent of the cases of right bundle branch block, the right ventricular contraction and the pulmonic pulse are delayed over the left ventricular and the aortic pulse by about 0.03 to 0.05 sec (Fig. 11-38). If there is hypertrophy of the right ventricle or intraventricular block of the right side, the delay is greater. Hypertension of the lesser circulation increases the delay revealed by the rise of the pulse, decreases that revealed by the incisura. Systemic hypertension may partly neutralize the effect of right bundle branch block, so that the delay is less apparent.

In both types of block, a prolongation of the phase of isometric relaxation was observed. A large percentage of cases of bundle branch block, whatever the side, seem to present a bilateral delay of contraction upon EKy studies. Phonocardiographic studies reveal a much larger percentage of asynchronism than EKy studies.

## 11-98 RATE, RHYTHM, AND CONDUCTION DISTURBANCES

been stopped with quinidine, preexcitation complexes may not appear as long as the quinidine effect persists; an electrocardiogram repeated several days after termination of treatment is therefore more likely to disclose preexcitation (Blinder et al.). The ultimate goal

in the treatment of tachycardia due to preexcitation would be to remove surgically the accessory bundle or the point of intimate contact between atrial and ventricular muscle. Its precise localization can be made satisfactorily from the configuration of the delta wave.

# Double rhythms (pararrhythmias)

CORNILIO PAPP

One of the basic laws of cardiac physiology is that "a pacemaker working at a faster rate suppresses any potential secondary or tertiary pacemaker having a lower rate." Since, under normal conditions, the SA node forms impulses at a faster rate than the AV node or the intra-ventricular centers, in normal conditions it remains in sole control of cardiac rhythm.

In double rhythms, two pacemakers are active simultaneously, one of which is usually the SA node. The secondary pacemaker, which may be situated anywhere in the atria, the node, the bundle, or its branches, may form impulses at a higher or lower rate than the SA node. For the existence of a double rhythm, it is essential that the slower pacemaker be protected from the faster one. Such a "protection block" has been shown to exist and prevents the suppression of the rhythm created by the SA node or the ectopic pacemaker, whichever is the slower of the two.

Double rhythm may manifest itself in two different forms:

1 *AV dissociation* Here the rhythm of the atria is directed by the SA node, that of the ventricles, by the AV node. The SA rhythm, usually slower, is protected by a unidirectional block which prevents the nodal impulse from spreading backwards to the SA node, while there is no obstacle to the spreading of sinus impulses to the AV node. The conducted SA impulses produce a transient disturbance of the AV nodal rhythm (dissociation with interference).

2 *Parasytote* The SA node is in command of atria and ventricles. An ectopic (usually ventricular) pacemaker working at a slower

rate, is protected by a block of entry from the faster SA impulses. This block, too, is unidirectional and allows the ectopic pacemaker to assert itself and to interfere with the basic rhythm.

The main difference between these two double rhythms—apart from the dissociated activity of the two pairs of chambers in AV dissociation—consists in the way the two pacemakers interfere with each other. In AV dissociation, it is the SA node which disturbs the ectopic pacemaker, while in parasytote, it is the ectopic pacemaker which interferes with the SA rhythm.

## ATRIOVENTRICULAR DISSOCIATION

When the rate at which impulses form in the AV node is superior to the rate at which it receives impulses from the SA node, AV nodal rhythm results. This condition arises when impulse formation is depressed in the SA node or exalted in the AV node, or when both these conditions exist. Since the physiologic property of the nodal tissue is that of unidirectional conduction, and impulses are transmitted readily from atrium to ventricle (but only with difficulty in the reverse direction), retrograde block may arise and the SA node will continue to beat independently. How many of the SA impulses are so timed as to fall outside the refractory period and "capture" the ventricle depends upon the relative rates of the two pacemakers and the duration of the refractory period of both the junctional tissues and the ventricles. If the AV nodal rhythm is rapid, the refractory period shortens, and, with a slow SA rhythm, ventricular

tached at all. The septal leaflet may or may not be attached. The new "tricuspid orifice" may be small or large and may be normal functionally or the seat of an insufficiency or, less commonly, stenosis. There is usually a patent foramen ovale. The right atrium is hypertrophied and dilated. The proximal part of the right ventricle is dilated. The distal part of the right ventricle may be hypertrophied or normal in thickness. The left atrium and ventricle may be normal or hypertrophied. The pulmonary artery is usually small. Fibroelastosis is often present in the proximal right ventricular chamber. The conduction system may be normal, or accessory muscle bundles may bridge the right atrium and ventricle.

**PATHOGENESIS OF THE COMPLEX.** The displaced tricuspid orifice may be considered to be the basic anomaly. Thus, the right atrium and proximal part of the right ventricle act as a unit, although the exact method of their functioning is not clear. There is usually decreased pulmonary flow. If there is a functional tricuspid stenosis, then there is a venoarterial shunt at the atrial level, and hence the left atrium and ventricle may present a volume hypertrophy, if not counterbalanced by the decreased pulmonary flow.

**Hypoplasia of the Aortic Tract Complexes.** In this group (Lev, 1953) the following common denominators exist (Fig 6-9A): (1) The aortic orifice, the ascending and the trans-

Fig. 6-8

atresia B

cuspid atr

right atrial and proximal right ventricular chamber C. Ebstein's disease. View of atrium, Pr, proximal chamber, C, conus (C D. From M. Lev Autopsy Diagnosis of Congenitally Malformed Hearts. Charles C Thomas, 1953)

verse portions of the aorta are small. (2) The pulmonary artery and its orifice are large. (3) The left side of the heart is hypoplastic. (4) The right side of the heart is markedly enlarged. (5) There is a widely patent ductus. (6) There is an atrial septal defect. (7) There is no transposition of the arterial trunks. In the simplest form, the above are the findings with a functioning left ventricle and no fibroelastosis. In another form, there is aortic stenosis or atresia with a small, but functioning, mitral orifice. Here the left ventricle is small, with fibroelastosis. In still another form, there is combined aortic and mitral atresia with a minute nonfunctioning left ventricle.

**PATHOGENESIS OF THE COMPLEX.** The embryogenesis of this complex is discussed in Chap. 1. After birth, there is increased pulmonary flow and hence left atrial flow. This is shunted through the atrial septal defect, producing a volume hypertrophy superimposed on the pressure hypertrophy of the right ventricle, produced by the "reversed" ductus. Where there is mitral and aortic atresia, this process is greatly exaggerated.

**Coarctation of the Aorta Complexes.** In coarctation of the aorta (Mustard et al., 1955; Reifenshtein et al.), there is a narrowing in some part of the aorta, usually the isthmus, although the narrowing may be present in the thoracic or the descending aorta. Where it is

present in the isthmus, there are two types of complexes associated with this abnormality—the adult (postductal) and the fetal (preductal) types.

**ADULT TYPE.** In the adult type of complex, the narrowing is usually just distal to the point of entry of the ductus or *ligamentum arteriosum*, but it may be present just at, or proximal to, the ductus (Fig. 6-9B). Uncommonly, an adult form may have the constriction beginning at the innominate or left subclavian and becoming gradually more severe at the approach of the ductus, or the initial constriction may be followed by dilatation and then constriction again. Occasionally, eventually, there may be complete atresia of part of the transverse arch. In this form of complex, the left ventricle is hypertrophied and there is dilatation of the ascending aorta. In about 10 per cent of the cases, there is a *patent ductus arteriosus*, usually of small caliber. There may be an associated *aneurysm of an aortic sinus of Valsalva* and a *bicuspid aortic valve* and, occasionally, a *left superior vena cava*. After 12 years of age, the intercostal arteries become enlarged and tortuous. The aortic ring may become dilated, with resultant aortic insufficiency. Likewise, the aorta distal to the constriction is often dilated.

**PATHOGENESIS OF THE COMPLEX.** There is *hypertension proximal to the coarctation*, with

Fig. 6-9. A. Hypoplasia of the aortic tract complex. Anterior view. A, aorta; P, pulmonary artery. B. Adult coarctation in a child. Arrow points to the coarctation. (From M. Lev. *Autopsy Diagnosis of Congenitally Malformed Hearts*. Charles C Thomas, 1953.)

## 11-98 RATE, RHYTHM, AND CONDUCTION DISTURBANCES

been stopped with quinidine, preexcitation complexes may not appear as long as the quinidine effect persists; an electrocardiogram repeated several days after termination of treatment is therefore more likely to disclose preexcitation (Blinder et al.). The ultimate goal

in the treatment of tachycardia due to preexcitation would be to remove surgically the accessory bundle or the point of intimate contact between atrial and ventricular muscle. Its precise localization can be made satisfactorily from the configuration of the delta wave.

# 11-108 RATE, RHYTHM, AND CONDUCTION DISTURBANCES

to drugs, and 8 with unexpected standstill, usually occurring during surgery (Zoll, et al., 1956a).

The first condition to be considered, Stokes-Adams attacks, occurs in patients with AV block and consists of attacks of cerebral ischemia due to very slow idioventricular rates, ventricular standstill, ventricular tachy-

cardia, or ventricular fibrillation (Parkinson et al., 1941). The attacks are manifested by dizziness, syncope, prolonged unconsciousness, and convulsions, and they may end in death. The cardiac origin of such seizures becomes clear when cardiac arrest is observed during an attack, by the absence of a pulse or heart sounds. A more exact diagnosis is usually

Fig 11-47. External electric stimulation in a patient with Stokes-Adams attacks. Lead aVF; standardization half-normal (1 mv equals 5 mm) A Interruption of idioventricular rhythm by faster externally paced beats. The intensity of the electric stimuli, E, was progressively increased until ventricular responses, V, were produced. Three spontaneous idioventricular complexes (cycle length,  $R-R = 0.4 \text{ sec}$ ) occurred during ineffective stimulation; during effective stimulation at a faster rate (cycle length,  $1.11 \text{ sec}$ ) they were suppressed. B. Resumption of idioventricular pacemaker reappeared after a pause of 4.64 sec and regained its previous rate within three beats. C. Effective stimulation at varying rates. Each stimulus, E, produced a ventricular response, V. Each electrocardiographic ventricular response depended upon an electric stimulus, as shown by the constant relationship at widely varying rates of stimulation. D. Ventricular standstill during temporary interruption of stimulation. During a test period of 5.5 sec no stimuli were applied. No spontaneous ventricular contractions occurred during this interval, and the patient lost consciousness. Resumption of stimuli immediately gave ventricular responses, and the patient revived at once. (Reprinted by permission of Grune & Stratton, from *Circulation*, 1954.)

made by the observation of a very slow heart rate due to an idioventricular rhythm between attacks, however, it is important to remember that evidence of any degree of AV block between attacks establishes the diagnosis and that, at times, in a patient with this disease, the pulse rate may be normal and AV conduction may be normal, with a P-R interval of less than 0.20 sec.

There are three major problems in the treatment of Stokes-Adams attacks: (1) emergency resuscitation from a major attack, (2) termination of persistent ventricular standstill, and (3) prevention of frequently recurrent attacks.

For a major attack with persistent syncope, emergency resuscitation must be effected promptly and the circulation to the heart and brain must be restored within 3 or 4 min. Electrocardiographic identification of the mechanism of the attack is useful but, even when an electrocardiogram is not available, treatment must be immediately instituted.

If the mechanism of the attack is ventricular standstill or is unknown, the precordium should be struck forcefully. Then cardiac puncture should be performed, the tip of the needle should be embedded in the heart wall, and the hub of the needle should be tapped sideways repeatedly to stimulate ventricular beats. If arrest persists, epinephrine hydrochloride may be injected through the needle into a cardiac chamber, care being taken not to put any within the myocardium.

These measures should be tried in sequence if there is delay in applying the electric pacemaker. They are simple and usually immediately feasible, but are frequently ineffective and sometimes produce fatal complications. The electric pacemaker, on the contrary, is completely safe and is uniformly effective in terminating attacks due to slow idioventricular rates or ventricular standstill. As soon as possible, therefore, the electric pacemaker should be attached to the patient and stimuli of increasing intensity applied until cardiac responses occur (Fig 11-47). If adequate intrinsic ventricular activity appears following resuscitation, stimulation may then be stopped. However, if there is excessive delay in applying the cardiac pacemaker, or if the mechanism is ventricular fibrillation, these measures will fail.

The author has now resuscitated over 200

patients from Stokes-Adams attacks with the electric pacemaker. In an early series of 50 cases, attacks due to very slow idioventricular rates were observed in 12 patients, and to ventricular standstill in 45 patients; these episodes of cerebral ischemia were all terminated immediately by electric stimulation. This dramatic effect was observed countless times. Stokes-Adams attacks due to ventricular tachycardia or fibrillation were seen in 20 patients. It is clear that such seizures cannot be terminated by stimulation. However, in 8 patients with frequent attacks due to multifocal ventricular tachycardia or fibrillation, continued external stimulation prevented their recurrence.

If adequate intrinsic ventricular activity fails to appear after successful resuscitation, a new, second problem is posed. It has heretofore been impossible to observe ventricular standstill for more than the few minutes that life would persist. For the first time, we have in the electric pacemaker a means of producing heart beats under such circumstances and of maintaining life indefinitely (as long as 109 hr in the author's experience). With the patient kept alive by the external pacemaker, there is no desperate emergency, and heroic and dangerous measures are unnecessary. With careful, deliberate infusions of diluted solutions of sympathomimetic amines, particularly epinephrine hydrochloride, the author was often successful in arousing an idioventricular rhythm, in accelerating it to an adequate rate, i.e., between 30 and 45 per minute, and in maintaining it there. He also used norepinephrine to maintain an adequate blood pressure whenever necessary.

The prevention of recurring attacks is a third major problem of Stokes-Adams disease that is still largely unsolved. When the idioventricular rate is too slow (below 30 per minute), ephedrine sulfate and isoproterenol (Isuprel) are often useful for long-term maintenance of heart rates between 30 and 45 beats per minute. When recurring attacks are due to varying AV conduction, atropine, ephedrine, and isoproterenol should be tried. When the attacks are due to recurrent ventricular tachycardia or fibrillation, ephedrine and isoproterenol again, or the cardiac pacemaker, may be useful in reducing ectopic activity by increasing the basic ventricular rate;

"captures" may not take place. But in the same case, slight variations of the rates may produce a shift in the responsive and refractory phases, and *interference beats* may appear. Thus, the distinction of AV dissociation with or without interference is purely artificial.

The term AV dissociation is often loosely applied to AV heart block. AV heart block is due to depression or interruption of conduction, while in AV dissociation, the SA impulse fails to reach the ventricle because of its arrival during the normal refractory phase following a previous impulse (Katz, 1946).

**Experimental Findings.** Rothberger and Winterberg (1910, 1912) have shown that the development of AV nodal rhythm in dogs is preceded by a short phase in which the atria are controlled by the SA node and the ventricles by the AV node. In other experiments, occasional SA impulses interfered with the ectopic pacemaker. Canter and Zahn (1912) obtained similar results. Scherf (1929) produced AV dissociation during aconitine intoxication. Luten (1925), in studies on digitalis intoxication in dogs, found that AV dissociation with a ventricular rate higher than the atrial rate preceded ventricular tachycardia. Van Bogaert (1933) arrived at similar conclusions with ouabain.

**Clinical Findings.** Wilson (1915) was the first to recognize AV dissociation with interference, and White (1916) described two further cases, to which another was added by Hewlett (1923). It was Mobitz (1923) who coined the term *interference dissociation*, which Scherf (1928) improved to *dissociation with interference*. Mobitz also gave a correct interpretation of the first case ever published but not recognized (Wenckebach, 1906). Lewis (1925) and Wenckebach and Winterberg (1927) published extensive reviews, these were brought up to date by Scherf and Schott (1953), Holzmann (1955), and Katz and Pick (1956).

Most cases were described in the course of acute rheumatic carditis, in which the incidence is about 10 per cent (Oettinger, 1935). Diphtheria (Korth and Schrumph, 1936) and other acute infections may also cause it. Digitalis overdosage as well as acute infections were considered in the cases of Bloom and Perlow (1930), Laubry and Lequime (1933), and Laubry and Puddu (1936). Scherf and

Boyd (1948) believe that dissociation with interference is rare in nondigitalized patients, but only 2 of the 12 cases of Cutts had digitalis. Quinidine sensitivity may also cause it (Linenthal et al., 1953). These factors often act in combination; simultaneous administration of quinidine and digitalis, operative trauma, anesthesia and digitalis—each was responsible in single cases of the author's series. It has also been observed with coronary heart disease and syphilitic aortitis, and exceptionally during hypertensive crises of adrenal tumors (Hegglin and Holzmann, 1937). While, in most of these cases, AV dissociation was transient, in a child of Ledoux and Aray (1936) with a normal heart, it had been persisting for years. Since persistent AV dissociation was observed in association with atrial septal defect, it may exist as a congenital variety (Papp, 1957).

The diagnosis is made through the electrocardiogram. The clinical impression is that of atrial extrasystoles, since the interfering beats are premature and are not followed by a compensatory pause. The irregularity also disappears on effort, for SA acceleration may temporarily abolish AV dissociation. The venous pulse may show *giant waves* when atrial and ventricular contractions coincide. Coexistent SA bradycardia may cause syncope.

**Electrocardiographic Patterns.** The varying SA rate (if SA arrhythmia is present), the coexistence of latent or partial heart block, the tachycardia caused by an irritable AV node, the variations of the refractory period of the junctional tissues and the ventricles, the transition into AV nodal rhythm may cause most intriguing tracings of complex arrhythmias.

The common pattern of AV dissociation with interference is shown in Fig. 11-43A. The average atrial rate is 90 and, therefore, slower than the average ventricular rate at 110, there is SA arrhythmia, while the AV nodal rhythm, except for the beat following the conducted sinus impulse, is regular. The third to eighth and last ventricular complexes are transmitted to the ventricle with a normal P-R interval and are premature. Only P waves falling on top of the T wave (end of the refractory phase) are conducted. The two rates are so aligned that no P waves fall in late diastole and can reach the ventricle. The three conducted beats form the only link between the SA and AV nodal rhythms.

quinidine and procaine amide are contraindicated in these patients with heart block and Stokes-Adams disease.

It is for this reason that a clear distinction should be made between patients with AV block who have Stokes-Adams attacks and patients without AV block who may have disturbances of ventricular rhythm. Episodes of ventricular arrhythmias that cause cerebral ischemia in the latter patients should not be called Stokes-Adams attacks but rather *cardiac syncope*, a much more general term. In them, there is no contraindication to quinidine and procaine amide.

Despite all the author's efforts and this new approach, many of the patients have died of Stokes-Adams attacks. These fatalities occurred because the electric pacemaker was not applied during a fatal attack when the episode occurred unexpectedly; because the attack was due to ventricular tachycardia or fibrillation and was not terminated by the electric pacemaker; or because of irreversible cerebral damage due to delay in applying electric stimulation. Several patients died of complications of their Stokes-Adams disease or of other primary disease, such as acute myocardial infarction, acute bacterial endocarditis, cardiac tamponade from multiple cardiac punctures, and congestive heart failure.

Episodes of cerebral ischemia due to ventricular standstill or fibrillation also occur in patients without Stokes-Adams disease. Certain of these episodes, as in the carotid sinus syndrome, are usually transitory, and are clearly due to reflex vagal stimulation. The distinction between Stokes-Adams attacks and reflex vagal standstill is of clinical importance because of differences in the course, prognosis, and treatment of each condition. Again, this distinction is usually simple but ultimately depends upon the presence or absence of AV block at any time between attacks.

External electric stimulation was repeatedly effective in resuscitating three patients with ventricular standstill due to reflex vagal stimulation. In all of them, episodes of ventricular arrest repeatedly interrupted normal sinus rhythm abruptly, producing syncope and convulsions. The precipitation of such episodes by carotid sinus pressure and their disappearance following the administration of atropine sulfate established their reflex vagal origin. More

than 100 times, in these patients, external electric stimulation terminated ventricular standstill and restored an effective circulation.

A third type of cardiac arrest occurs as a result of depression of cardiac automatism due to drugs. The author has observed three patients with attacks of syncope due to digitalis. With digitalis toxicity, SA block occurred, whereupon cardiac activity was maintained by nodal or ventricular pacemakers, intermittent failure of these pacemakers resulted in periods of ventricular standstill lasting as long as 1 min. External electric stimulation resuscitated the patients several times. With recession of the digitalis effect, the seizures stopped.

Two patients with ventricular standstill following intravenous administration of procaine amide in the treatment of ventricular extrasystoles and tachycardia, have also been resuscitated promptly by other workers by means of the external electric pacemaker.

Cardiac arrest may also occur in a fourth group of patients. Young, healthy, individuals without heart disease may develop cardiac arrest unexpectedly, while undergoing various diagnostic and therapeutic procedures, particularly while under anesthesia in the operating room. Though infrequent, each such accident is a dreadful catastrophe.

The commonly recognized mechanisms of unexpected arrest are ventricular standstill or fibrillation, standstill is the usual cause, occurring probably about 90 per cent of the time, and reflex vagal stimulation appears to be a frequent precipitating factor.

Electric stimulation of the heart has been effective in 11 such cases of unexpected cardiac arrest. Three of these patients were observed by the author personally. The others were described to him in personal communications by the physicians concerned. The cases occurred during various procedures, 10 during surgery, 1 during pericardiocentesis. The cardiac arrest was terminated in each case by the electric pacemaker, so that thoracotomy and cardiac massage were not necessary. Eight of the 11 patients recovered completely; 2 died of unsuccessful cardiac surgery, and 1 died 5 hr after an abdominal operation.

The author's experiences with the cardiac pacemaker indicate that external electric stimulation can resuscitate the heart from arrest that occurs unexpectedly under anesthesia during

As soon as the SA rhythm slows, dissociation with interference appears. During maximal deceleration, SA bradycardia at an average rate of 39 develops; a bigeminal rhythm consisting of a nodal escape and a conducted beat keeps the ventricular rate at 80 (Fig 11-43B). When the vagal effect subsides, SA rhythm is again restored (last two cycles of Fig 11-44C). The P waves, which appear at a distance of 0.26 to 0.37 sec after the nodal escapes, are conducted to the ventricles at a speed of 0.31 to 0.34 sec (Figs 11-43D, E, and 11-44). This may suggest a reciprocal rhythm. However, if the P waves are magnified through use of a right atrial lead and double amplification, it becomes evident that all P waves are upright and of SA origin, and that there is no retrograde conduction (Fig 11-43D, E). Even so, the reactivation of the SA node after the nodal escape suggests that the latter is instrumental in this, either through a mechanical effect (White, 1921, Rosenbaum and Lepeschkin, 1955) or by improvement of the circulation in the SA node. If this is so, the two pacemakers also work in relay, the AV node reactivating the SA node and thus then taking over the lead for a few beats until a longer SA standstill occurs which provokes a nodal escape.

AV dissociation due to irritability of the AV node is rare and forms a link with paroxysmal tachycardia (Fig 11-45).

Contrary to Figs 11-43D, E, and 11-44, which show SA bradycardia, the basic disturbance is an ectopic atrial tachycardia at an average rate of 128 with 2:1 AV block and a P-R interval of 0.24 to 0.28 sec (Fig. 11-45, bottom row). Slight slowing of the SA rhythm produces an AV nodal dissociation, which, during two rates

soon equalize, slight slowing of the AV rhythm coincides with slowing of the SA rhythm (Fig. 11-45, top row), until a P wave falls late enough in diastole to capture the ventricles (sixth R wave). The dissociation, however, persists, even though the AV nodal rhythm has become slow; a P wave falling late in diastole remains blocked because of coexistent AV block. The same factors which produce an irritability of the SA node act on the AV node as well, which explains the alignment of the two rates during the tachycardic phase.

The association of 2:1 AV block with AV dissociation, but without nodal irritability, has a different electrocardiographic pattern. Conducted beats here have an aberrant pattern which appears when the SA rhythm slows. The ectopic center is emerging only when the half SA rate becomes less than the autonomic rate of the ectopic center. The number of impulses discharged by the SA node is of secondary

surgery or other procedures, just as it does from the other types of cardiac arrest. The technique has been applied safely in the operating room within the few minutes available for complete resuscitation. It seems to us, therefore, that external electric stimulation of the heart should be tried quickly, even in the operating room, before resorting to thoracotomy and cardiac massage.

In addition to these successful experiences, the author has personally attempted resuscitation with the cardiac pacemaker unsuccessfully in several patients who developed unexpected cardiac arrest, most, but not all, of them during anesthesia. A brief list of the procedures involved indicates their wide variety and frequently insignificant nature. They include jugular puncture, intravenous pyelography, bronchography, cardiac catheterization, endotracheal intubation, hip nailing, cholecystectomy, and thoracic and cardiac surgery. In a few, the circulatory arrest was due to ventricular fibrillation, and stimulation was ineffective. In all the others, electric stimulation was applied too late, over 5 min after onset of arrest, and usually after prolonged, ineffective massage.

These failures emphasize two critical problems of unexpected cardiac arrest. First, the responsiveness of the heart to stimulation diminishes progressively with continued anoxia. Second, effective ventricular beats cannot be stimulated by the pacemaker during ventricular fibrillation. The time interval between arrest and the resumption of effective ventricular output must be brief, probably less than 3 or 4 min, if cerebral and cardiac function is to return unimpaired. Avoidance of excessive delay depends upon immediate recognition of the cardiac arrest and then the immediate application of external stimulation and institution of a prearranged program for resuscitation.

Immediate recognition of arrest at its onset depends upon continuous monitoring of cardiac activity. The author has developed a practical monitoring device<sup>2</sup> combined with the pacemaker, and has used it to great advantage in the operating room and in patients with recurring Stokes-Adams attacks, to signal immediately the cessation of heart beats.

<sup>2</sup> Manufactured by the Electrodyne Company, Norwood, Mass.

Briefly, the monitor amplifies the electric activity of the heart like an electrocardiogram, so that patient contact and pickup of impulse are not difficult, *it gives an audible as well as a visual signal of each beat*, so that undivided attention to the monitor is not needed, and *it rings a compelling alarm* with the onset of arrest. Furthermore, it shows the mechanism of the arrest promptly, so that there is no problem in differentiating ventricular standstill from fibrillation. If standstill is seen, stimulation with the pacemaking half of the machine can be effected without delay through the same electrodes on the chest. Ideally, perhaps, such a monitor-pacemaker should be applied routinely to all patients under anesthesia. Certainly the monitor-pacemaker should be applied beforehand to all patients undergoing anesthesia who present a particularly high risk of cardiac arrest. This specially vulnerable group includes patients with extreme debility, severe heart disease of any kind, AV block of any degree, patients receiving large doses of quinidine or procaine amide, patients with high serum potassium, patients with a sensitive carotid sinus, patients undergoing surgery involving the extraocular muscles, and particularly patients who have had previous episodes of cardiac arrest.

Immediately upon recognition of arrest, a rehearsed program of treatment should be instituted. The heart should be stimulated mechanically by striking the precordium forcefully, by cardiac needle puncture, or by cardiac manipulation through the diaphragm, *if the abdomen is open*. These measures are simple and immediately feasible and are worth the few seconds necessary because they are occasionally effective. If no time has been lost in the recognition of arrest, it is proper to spend no more than 1 min in attaching and trying the cardiac pacemaker. This trial, which should be successful in most cases of ventricular standstill, can be made easily within this time limit if the electric pacemaker is close at hand and if the operating room personnel have been trained in its use by previous emergency drills.

If the initial mechanism of cardiac arrest is ventricular fibrillation or if the patient is not resuscitated by external mechanical or electric stimulation, the chest must be opened promptly and cardiac massage begun. At the

11-43A) because of different spread of the SA impulse in the bundle. The P-R interval of the SA beats may be normal (Fig. 11-43A) or prolonged (Figs. 11-43, 11-44, 11-45). The prolongation may be due to latent heart block (long P-R interval), early conduction before complete recovery of the bundle takes place, or both. There is an inverse time relationship between the R-P period and the P-R interval of the conducted beat (Katz, 1946; Katz and Pick, 1956). The later the P wave appears in diastole, the faster is the AV conduction. In Fig. 11-43E, the P waves appearing on top of, or shortly after, the preceding T wave are conducted to the ventricle at a speed of 0.90 or 0.92 sec, the P waves appearing later in diastole are conducted in 0.24 sec, which was the fastest conduction time of this patient, who had latent heart block. Latent heart block is frequently found in AV dissociation and is a predisposing factor, for impairment of forward conduction favors the development of retrograde block. The distance between the conducted ventricular complex and the following AV nodal beat is usually the same as between two nodal beats, since nodal automatism is quickly restored (Figs. 11-43D, E, and 11-44), but it may be shorter (Fig. 11-43A) or longer.

The shortening has been explained by Schief and Schott (1953) by the late appearance of the SA beat because of delayed conduction in the bundle (see slight aberrance in Fig. 11-43A) while the nodal beat is on time. If the distance is slightly prolonged, it is due to fatigue of the conducting system; if the pause is longer and is equal to the distance between a conducted P wave and the next nodal wave, following a conducted ventricular complex, one has to assume that concealed conduction (Langendorf, 1948) has taken place. This means that the sinus impulse reached the AV node, destroyed the immature AV impulse, and was blocked on its way to the ventricles, so that it did not become electrically visible. The same phenomenon was earlier described by Korth (1941) as incomplete interference, and explained by Schott (1937) as a sign of impaired conduction in the bundle.

AV dissociation may appear as a pause in ectopic rhythm through SA bradycardia or SA block, it can then be temporarily abolished by exertion (Fig. 11-44A).

Fig. 11-44. Same case as in Fig. 11-43D. Lead II. A. End of exercise test; after the fourth beat, incomplete AV dissociation. B. 16.5 sec after the end of (A), sinus bradycardia and bigeminal rhythm formed by a nodal beat and a conducted beat during maximal deceleration. R<sub>7</sub>, which is early, shows aberrant conduction. C. 23 sec after the end of (B), bigeminal rhythm gradually subsiding, conducted beats alternating with AV nodal beats in the second half of (C). Full lines, transmitted impulses; interrupted lines, no conduction. (Permission of the British Heart Journal.)

same time the anesthetist must provide adequate respiratory exchange of oxygen. Once blood is being squeezed out of the heart by the surgeon's hand, the desperate urgency of the 3-min time limit is over and further measures can be undertaken, if necessary, with more care and deliberation.

If the ventricular fibrillation appears or persists in spite of effective massage, *defibrillation* should be attempted only after the myocardium becomes pink and firm, *countershock* with a 60-cycle alternating current of 120 to 150 volts for 0.15 sec applied across large electrodes on the heart is most effective for this purpose.

Ventricular standstill may persist despite effective massage or may recur following defibrillation. *Epinephrine hydrochloride* (1 ml of a 1:10,000 dilution) may be injected into the left atrial chamber and may be repeated in 3 min if necessary. If standstill continues and the myocardium is flabby, 5 ml of 10 per cent *calcium chloride* may be given. For persistent standstill, the electric pacemaker may be applied directly to the heart with a special bipolar electrode, so that massage need not be continued too long.

If resuscitation is successful, the patient should be kept under constant observation for 2 or 3 days, because arrest frequently recurs. The cardiac monitor-pacemaker is most useful in providing continuous information about cardiac activity during this time and in providing immediately available, effective resuscitation from standstill. In the last year we have saved two patients from recurrent arrest in this way.

The second mechanism by which cardiac arrest may occur is *ventricular fibrillation*. Countershocks of 60-cycle alternating current of 50 to 150 volts and for 0.1 to 0.2 sec applied across the exposed heart have been used for some time as an adjunct to cardiac massage to stop ventricular fibrillation. Recently the author and others have used similar countershock current of higher voltage experimentally to stop ventricular fibrillation by applying it *externally* across the unopened chest (Guyton et al.) The author has applied such high-voltage countershocks repeatedly in the experimental animal without producing damage to the heart, nervous system, or skin.

Furthermore, he found that externally ap-

plied countershock would also terminate atrial fibrillation, atrial tachycardia, nodal tachycardia, and ventricular tachycardia as well as ventricular fibrillation. The efficacy of the external countershock was clearly established by the repeated observation of the instantaneous cessation of these arrhythmias upon application of the electric current (Zoll, 1956c).

After these successful experimental observations, this technique was applied to ventricular fibrillation in man (Zoll, 1956b). The author has now stopped ventricular fibrillation twenty times in 11 patients. However, all but 1 of these patients died. In each fatal instance the countershock was applied after considerable delay (5 min or more), and effective beats did not return after defibrillation. It was recognized beforehand in most of these cases that the procedure had little chance of saving the patient because of the long delay. The underlying causes of fibrillation in these cases were acute myocardial infarction, digitalis intoxication, and Stokes-Adams attacks.

One patient survived. He had active Stokes-Adams attacks and was resuscitated from many episodes of ventricular standstill by the electric pacemaker, and from three episodes of ventricular fibrillation by external countershocks of 270 to 360 volts. In each instance the countershock was applied within 3 or 4 min after the onset of the fibrillation. Ventricular standstill occurred after each defibrillation, but external electric stimulation then evoked effective ventricular beats, which were followed shortly by an intrinsic ventricular rhythm and complete recovery. Figure 11-45 shows the electrocardiograms taken during one of these episodes. In the last year, the author has successfully resuscitated 8 patients over 400 times from ventricular tachycardia or fibrillation by external electric countershock.

The termination of atrial fibrillation, supraventricular tachycardia, and ventricular tachycardia by external countershock, in addition to the possibility of external defibrillation, has wide clinical potentialities that have not been completely explored. This technique may prove useful in desperate cases resistant to drug therapy, by providing a means of immediate termination of the arrhythmia without the dangers of prolongation of the arrhythmia and in those connected with massive drug administration.

ectopic beats is a multiple of a common denominator representing the cycle length of the ectopic rhythm. This can be easily calculated if two extrasystoles are seen in sequence; if they are separated from each other by longer stretches containing SA beats, the refractory period has to be determined on the basis of the shortest "coupling" separating the extrasystole from the previous SA beat. The latent beats have to fall within the refractory period, which may be much longer than the Q-T period, especially when the rate of both the SA and the ectopic pacemaker is slow. An example is shown in Fig. 11-46, where the SA rate is 43 and the ectopic rate is 34. The shortest "coupling" over long stretches of records was 0.76 sec (Fig. 11-46), all ectopic impulses following at a shorter distance after the previous SA impulse remain latent (interrupted vertical

arrows). The parasystolic center shows more irregularity than usually observed—the cycles should not vary by more than 0.05 sec (Pick, 1933)—yet the varying "coupling" and the identical shape of extrasystoles make the diagnosis certain.

More than one parasystolic center may be active simultaneously (Holzmann, 1933); cases of atrial parasystole have also been described (Scherf and Schott, 1933). The parasystolic center may appear only intermittently when both rates are stable and so linked with each other that the ectopic impulses mostly fall during the refractory period. Carotid sinus pressure may suppress the SA rhythm, the parasystolic rhythm remaining in sole control (Mueller and Baron, 1953). Amyl nitrite in-

The demonstrated efficacy of external countershock in stopping ventricular fibrillation in an provides a readily available and safe technique for stopping this usually fatal arrhythmia. Outside the operating room and in seriously ill patients in whom thoracotomy and cardiac massage may be particularly inadvisable, external countershock may offer the only effective therapy. In the operating room, continuous cardiac monitoring, immediate external electric stimulation, and external electric defibrillation make up a combined technique by which unexpected cardiac arrest may be recognized promptly, and the patient may be resuscitated from ventricular standstill or fibrillation, before resorting to the more formidable and traumatic procedure of cardiac massage.

The major difficulty with external electric cardiac stimulation is that the electric shocks which stimulate ventricular responses are often

very painful. Although this pain is not important in the emergency resuscitation of an unconscious patient from cardiac arrest, it is often very distressing when patients require prolonged or repeated stimulation for repetitive seizures, persistent absence of intrinsic ventricular beats, excessively slow idioventricular rates, or prevention of recurring ventricular tachycardia or fibrillation. These problems arise most in patients with Stokes-Adams disease, whether it occurs naturally from cardiac disease or whether it follows cardiac surgery, particularly the repair of interventricular septal defects.

Several approaches to this problem of pain with stimulation have been developed. In the first place, analgesic agents like meperidine (Demerol) often make the pain more tolerable. Furthermore, careful application of the electrodes to the chest wall with moderate rubbing of the skin may lower the threshold for

Fig 11-48 Resuscitation from ventricular fibrillation in a patient with Stokes-Adams attacks. Lead aVF, amplification half-normal (1 mv = 5 mm). A. Patient's usual idioventricular rhythm before seizure B. Ventricular fibrillation that persisted after application of countershock of 300 volts. The indicated times are from the beginning of the continuous electrocardiogram, 1 min after the episode began. The broken line indicates when the electric activity of the heart was not being recorded ("instamatic" switch turned on) C. The two strips are continuous. External countershock of 360 volts at 97 sec terminated the arrhythmia and produced ventricular standstill. External electric stimuli, E, at 150 volts produced ventricular beats, V, 12 sec later. D. Resumption of usual idioventricular rhythm within a few seconds after termination of electric stimulation. The patient regained consciousness promptly and recovered completely. (From Zoll, New England J. Med. 1956)

importance; it is the number of impulses reaching the bundle which determines the activity of the secondary pacemaker (Oettinger, 1935; Dressler et al., 1952).

Transition from AV dissociation to AV nodal rhythm is not uncommon (Fig. 11-43B); the two arrhythmias are interrelated, and the difference consists only in the presence or absence of retrograde block. AV dissociation may also appear as a transient phase under quinidine treatment for atrial fibrillation before SA rhythm is established. It is often observed during acute rheumatic fever in combination with almost any arrhythmia (Bain, 1939; Vakil, 1954).

**Prognosis and Treatment.** Prognosis depends on the underlying cause. AV dissociation has little significance if it appears in a patient with otherwise healthy myocardium, but this is rarely the case. Its appearance during infections means cardiac injury, which may be slight or severe, its persistence after subsidence of rheumatic arthritis is a warning that carditis is still active. Should it develop during treatment with digitals or quinidine, the drugs should be stopped, for the disturbance is evidence of toxicity.

Treatment has no place in AV dissociation. When the latter arises as a passive ectopic rhythm, it is an expression of a normal cardiac mechanism brought into play by depression of primary impulse formation. Syncopal attacks due to SA bradycardia cease as soon as nodal automatism is established. If AV dissociation is due to nodal irritability, treatment should be that of paroxysmal tachycardia.

## PARASYSTOLE

Parasystole, like AV dissociation, involves the concept of two simultaneously and independently acting pacemakers, one of which is in the SA node, the other usually in one of the ventricles. Such a possibility was first shown to exist by Fleming (1911). He imagined that the ectopic focus lies in "what may be called a backwater of primitive cardiac tissue" and that "physiological stimuli passing down the main channel are unable to disturb the point where ventricular stimuli arise", thus, the slower ventricular focus remains protected from the faster SA impulse. A protective block was assumed by Kaufmann and Rothberger (1919), who later (1922) made the first extensive study

of the coexistence of two independent centers of impulse formation. In cases with ventricular rhythm faster than that of the SA pacemaker, it was thought that there might be an *exit block* which prevents the dominance of ectopic pacemaker and the transformation of parasystole into ventricular tachycardia. The term "block" applied in this sense is a misnomer, for the emphasis is not on inhibited conduction but on diminished excitability; excitability in relation to strength of the dominant rhythm determines the function of the ectopic center (Scherf and Chick, 1951).

Scherf (1927) was able to produce short periods of parasystole in dogs by mechanical and electrical stimuli after reduction of cardiac excitability with quinidine or sensitization of the heart with barium chloride and aconitine. Longer-lasting parasystole, without mechanical stimulation, was produced by application of veratrine; parasystole so produced fulfilled most of the clinical criteria.

Parasystole is rare, its incidence being about 0.04 per cent of all routine ECGs recorded in a general hospital (Scherf and Boyd, 1950). It is mainly observed in coronary heart disease and is believed to be always evidence of an abnormal heart, except for the exceptional cases of nodal parasystole (Pick, 1953). Whether this belief can be upheld is questionable, since cases with normal hearts have been described (Singer and Winterberg, 1920; Heinz and Edridge, 1957). Scherf and Schott (1953) found 11 cases without structural heart disease among 49. Most of the patients with organic heart disease were experiencing heart failure and were receiving digitals, stopping the drug abolished the ectopic rhythm (Holzmann, 1935).

**Electrocardiographic Patterns.** The common electrocardiographic pattern is that of ventricular extrasystoles of identical shape. These appear at a varying distance from the SA beat and, therefore, are not induced by it, the "coupling" is variable, as opposed to the usual form of extrasystole to be observed in bigeminal rhythm. In fact the term "coupling" should not be applied, since the ectopic beats appear as cycles of an autonomous rhythm, the emergence of which is regulated by the refractory phase of the dominant rhythm. When SA and ectopic impulses fall together, fusion beats result, having an intermediate shape between ectopic and SA beats. The final proof of parasystole can be given if the distance between two

stimulation with consequent reduction in the amount of pain.

A second approach has proved most useful in the management of atrioventricular block and cardiac arrest that follow cardiac surgery and constitute a major complication of open-heart surgery. A modification of the technique of external electric stimulation of the heart was introduced (Weirich et al., 1958), by stimulating the heart directly with an electric pacemaker. At the time of surgery, a wire is inserted into the myocardium and brought through the skin, where it is attached to an electric stimulator, and a second wire from the pacemaker is placed subcutaneously to complete the electric circuit. Effective cardiac stimulation is possible by way of the myocardial electrode at voltages (usually well below 10 volts) that do not produce any pain or skeletal muscular movement. This type of direct cardiac stimulation can be used freely and most effectively in the management of postoperative heart block for several weeks after surgery; in most instances, during this time, normal sinus rhythm returns and the difficulty is completely solved. In addition to the requirement of open thoracotomy to place the electrode, this technique does have two limitations. Infection may occasionally occur at the site of exit of the wires through the skin. Secondly, stimulation via the myocardial electrode becomes ineffective, usually within 8 weeks or less, apparently because of inflammatory reaction about the myocardial electrode. These difficulties make this method unsuitable for the long-term management of patients with Stokes-Adams disease.

Two interesting modifications of Lillehei's direct myocardial stimulation have been intro-

duced to obviate the necessity for thoracotomy. One has been the introduction of a myocardial electrode by Thevenet et al. (1958) through a blind percutaneous puncture. This technique carries with it the risk and uncertainty of a blind puncture of the heart plus the original limitations of cutaneous infection and ultimate ineffectiveness of stimulation within a month or two.

The second modification, by Furman and Schwedel, is the introduction of an *intracutaneous wire electrode* by way of a cardiac catheter passed up a vein of the forearm into the right ventricle. Direct cardiac stimulation at voltages less than 10 volts without pain was carried out by him in one patient with Stokes-Adams disease for over 3 months. Local skin infection is a problem with this technique also, but effective stimulation is apparently possible for longer periods than with the myocardial electrode. The additional possible complications of thromboembolism and trauma to the right-sided endocardium or valves were not encountered, anticoagulant therapy was maintained throughout the entire period of stimulation. This procedure is clearly most useful in patients with Stokes-Adams disease with persistent seizures, who cannot tolerate external electric stimulation. Under these circumstances, the risks of the procedure are clearly acceptable. It is equally clear, however, that this technique cannot be used indefinitely for the permanent maintenance of patients with Stokes-Adams disease throughout their lifetime. Better techniques of management, by pharmacologic agents or by electronic pacemakers that may be buried in the body and operate effectively and indefinitely, are under investigation for this ultimate goal.

ectopic beats is a multiple of a common denominator representing the cycle length of the ectopic rhythm. This can be easily calculated if two extrasystoles are seen in sequence, if they are separated from each other by longer stretches containing SA beats, the refractory period has to be determined on the basis of the shortest "coupling" separating the extrasystole from the previous SA beat. The latent beats have to fall within the refractory period, which may be much longer than the Q-T period, especially when the rate of both the SA and the ectopic pacemaker is slow. An example is shown in Fig. 11-46, where the SA rate = 43 and the ectopic rate is 34. The shortest "coupling" over long stretches of records was 0.76 sec (Fig. 11-46); all ectopic impulses following at a shorter distance after the previous SA impulse remain latent (interrupted vertical

arrows). The parasystolic center shows more irregularity than usually observed—the cycles should not vary by more than 0.05 sec (Pick, 1957)—yet the varying "coupling" and the identical shape of extrasystoles make the diagnosis certain.

More than one parasystolic center may be active simultaneously (Holzmann, 1935); cases of atrial parasystole have also been described (Scherf and Schott, 1953). The parasystolic center may appear only intermittently when both rates are stable and so linked with each other that the ectopic impulses mostly fall during the refractory period. Carotid sinus pressure may suppress the SA rhythm, the parasystolic rhythm remaining in sole control (Mueller and Baron, 1953). Amyl nitrite in-

# Clinical differentiation of cardiac arrhythmias

RUSTOM JAL VAKIL

**Nomenclature.** The term *normal sinus rhythm* implies a regular rhythm of from 60 to 100 beats per minute, initiated at the SA node. Any deviation from normal has been referred to as *cardiac arrhythmia*, irrespective of whether the abnormal rhythm was regular or irregular. Such a procedure of labeling a perfectly regular rhythm, such as that of complete heart block, paroxysmal tachycardia, sinus bradycardia, or atrial flutter, as "cardiac arrhythmia" is definitely unscientific. Hence, arises the need for more scientific designations, such as abnormal heart rhythms, abnormal cardiac mechanisms, disorders of the heart rhythm, or dysrhythmias.<sup>1</sup>

**Importance of Abnormal Heart Rhythms.** Abnormal heart rhythms are of clinical importance for several reasons: (1) their incidence is high in clinical practice, (2) they are a source of anxiety to both patient and doctor, (3) they often focus attention on the correct diagnosis of the disease, (4) their diagnosis is often an essential prerequisite to successful treatment, (5) they may predispose to complications or untoward events, (6) they may alter the prognosis or outlook of an existing cardiac condition, and (7) their prompt treatment may postpone or avoid the occurrence of cardiac failure.

<sup>1</sup> In order to avoid this confusing terminology, Lohsada (1949) suggested dividing these disturbances into (a) tachycardias, (b) bradycardias, and (c) arrhythmias. The complex of these disturbances he called "disturbances of the heart rate and rhythm."

**Anatomicophysiology Considerations.** From early embryonic life until death, the conducting system of the heart has the power of automatic and rhythmic contraction. The conducting system is a specialized neuromuscular tissue, endowed with the power of initiating and conducting cardiac impulses.

The heart beat is normally initiated by the SA node, which, in normal conditions, has an inherent rate of stimulus formation greater than that of any other component of the conduction system. It is, therefore, referred to as the *pacemaker* of the heart; in the event of its being depressed or diseased, a subsidiary or secondary pacemaker takes over the function of initiating beats (nodal or idioventricular pacemaker).

## CLASSIFICATION

Many different classifications of cardiac arrhythmias have been proposed from time to time, with alleged advantages, and later abandoned in favor of new ones. On the basis of the mechanisms involved, abnormal cardiac rhythms were classified into two major groups, viz., (1) disturbances of impulse formation (inclusive of various types of sinus or nodotopic and ectopic or heterotopic rhythms), and (2) disturbances of impulse conduction (inclusive of sinoatrial, atrioventricular, and intraventricular blocks) by Vakil and Gohwalla (1952).

The following classification of abnormal cardiac mechanisms or rhythms, recently proposed by the American Heart Association and based

halation may have an opposite effect through acceleration of the SA rhythm or improved blood supply (Holzmann, 1935).

*Parasystole with exit block* is said to exist when only some of the ectopic beats falling outside the refractory period become manifest. This usually happens in the rare cases where the rate of the ectopic centers is faster than that of the SA rhythm.

Though parasystolic rhythm should be strictly separated from bigeminal rhythm with fixed coupling, intermediate cases have been described. Holzmann believes that the same metabolic state of the cardiac muscle induced by digitals can cause reentry and parasystole;

constant coupling can be simulated by stability of the two rhythms. In the case of Mueller and Baron, coupled rhythm alternated with parasystole, and the authors believed that the ectopic impulses were not strong enough to emerge except during the supernormal phase of recovery. The reverse, i e, the production of induced extrasystoles by the ectopic pacemaker, has also been described (Scherf and Schott, 1951) and explained by "directional block" around the ectopic center.

Parasystole is an electrocardiographic curiosity and not a clinical state, since it has no hemodynamic importance. Prognosis and treatment depend on the causative factors.

stimulation with consequent reduction in the amount of pain.

A second approach has proved most useful in the management of atrioventricular block and cardiac arrest that follow cardiac surgery and constitute a major complication of open-heart surgery. A modification of the technique of external electric stimulation of the heart was introduced (Weirich et al., 1958), by *stimulating the heart directly* with an electric pacemaker. At the time of surgery, a wire is inserted into the myocardium and brought through the skin, where it is attached to an electric stimulator, and a second wire from the pacemaker is placed subcutaneously to complete the electric circuit. Effective cardiac stimulation is possible by way of the myocardial electrode at voltages (usually well below 10 volts) that do not produce any pain or skeletal muscular movement. This type of direct cardiac stimulation can be used freely and most effectively in the management of postoperative heart block for several weeks after surgery, in most instances, during this time, normal sinus rhythm returns and the difficulty is completely solved. In addition to the requirement of open thoracotomy to place the electrode, this technique does have two limitations. Infection may occasionally occur at the site of exit of the wires through the skin. Secondly, stimulation via the myocardial electrode becomes ineffective, usually within 8 weeks or less, apparently because of inflammatory reaction about the myocardial electrode. These difficulties make this method unsuitable for the long-term management of patients with Stokes-Adams disease.

Two interesting modifications of Lillehei's direct myocardial stimulation have been intro-

duced to obviate the necessity for thoracotomy. One has been the introduction of a myocardial electrode by Thevenet et al. (1958) through a blind percutaneous puncture. This technique carries with it the risk and uncertainty of a blind puncture of the heart plus the original limitations of cutaneous infection and ultimate ineffectiveness of stimulation within a month or two.

The second modification, by Furman and Schwedel, is the introduction of an *intracavitary wire electrode* by way of a cardiac catheter passed up a vein of the forearm into the right ventricle. Direct cardiac stimulation at voltages less than 10 volts without pain was carried out by him in one patient with Stokes-Adams disease for over 3 months. Local skin infection is a problem with this technique also, but effective stimulation is apparently possible for longer periods than with the myocardial electrode. The additional possible complications of thromboembolism and trauma to the right-sided endocardium or valves were not encountered; anticoagulant therapy was maintained throughout the entire period of stimulation. This procedure is clearly most useful in patients with Stokes-Adams disease with persistent seizures, who cannot tolerate external electric stimulation. Under these circumstances, the risks of the procedure are clearly acceptable. It is equally clear, however, that this technique cannot be used indefinitely for the permanent maintenance of patients with Stokes-Adams disease throughout their lifetime. Better techniques of management, by pharmacologic agents or by electronic pacemakers that may be buried in the body and operate effectively and indefinitely, are under investigation for this ultimate goal.

# Cardiac resuscitation by external electric stimulation and countershock

PAUL M. ZOLL

*Cardiac arrest* presents a critical problem in many different clinical situations. It is a desperate emergency that requires prompt, energetic, and effective measures to effect resuscitation within the urgent time limit of about 4 min.

Therapeutic procedures in the past have included cardiac puncture, intracardiac injection of drugs, and thoracotomy with cardiac massage, but the results with all these procedures are unsatisfactory in that the complete recovery rate is usually about 30 per cent (Stephenson et al., Cole).

A complicating factor in the emergency treatment of cardiac arrest is that the mechanism of the arrest may be either ventricular standstill or ventricular fibrillation. These mechanisms cannot be differentiated by the usual clinical means but only by an electrocardiogram or by direct inspection of the exposed heart, they tend to occur in somewhat different situations, however, and, most important, they require different treatment.

*Ventricular standstill* occurs particularly in four clinical situations. (1) in the Stokes-Adams attacks which occur in patients with AV heart block, (2) during reflex vagal stimulation, as in patients with a hypersensitive carotid sinus, (3) during treatment with cardioactive drugs, such as digitalis, quinidine, and procaine amide, and (4) unexpectedly, during various diagnostic and therapeutic procedures, particularly in the operating room under anesthesia. *Ventricular fibrillation* may

occur in a Stokes-Adams attack, but it occurs most often as a disastrous complication of acute myocardial infarction.

The first problem to be considered in this chapter is ventricular standstill. Recently, the author has developed a new therapeutic approach to the problems posed by it. It is an externally applied cardiac pacemaker that produces effective ventricular beats, terminates ventricular standstill, and maintains an externally controlled rhythm for as long as necessary until spontaneous ventricular beats return. The electric stimulator functions like a natural intracardiac pacemaker but is under complete external control (Zoll, 1952). Figure 11-47 shows the electrocardiogram of a period of cardiac arrest terminated by electric stimuli and ventricular beats. The instrument<sup>1</sup> is easily applied and clinically practicable. Two dials permit variation of rate of stimulation, and of amplitude of stimulation from 0 to 150 volts. Output wires carry the electric stimuli to the electrodes, which are smeared with conductive jelly and held on the precordium (usually in the  $V_2$  and  $V_4$  positions) by plastic handles or a rubber strap. The electric shocks go through the chest wall and produce ventricular beats. This technique of external electric stimulation of the heart has now been used successfully by the author and others to resuscitate over 200 patients with Stokes-Adams attacks, 3 with reflex vagal stimulation, 4 with standstill due

<sup>1</sup> Manufactured by the Electrodyne Company, Norwood, Mass.

cardia most often occur in subjects under 40 years of age, those of ventricular tachycardia are more common after 40. Complete heart block, although usually found in persons over 50, may be noted in childhood, when its origin is congenital, diphtheritic, or rheumatic. Pre-

mitral disease or thyrotoxicosis, is more common

bladder disease, chronic gastritis, and order, or renal calculus is in favor of extrasystole. A history of coronary occlusion or precordial pain suggests the possibilities of ventricular extrasystoles, ventricular tachycardia, or AV block

**CAUSES AND ADDICTIONS** Overdigitalization may provoke extrasystoles, especially with a bigeminal type of sinus bradycardia, sinus arrhythmia, or AV block. Long-standing or excessive administration of epinephrine or ephedrine for bronchial asthma, of thyroid extract for obesity, or of atropine, quinine, or barium chloride may elicit extrasystoles, sinus tachycardia, or AV block. Excess of tea, coffee, or tobacco may be responsible at times for troublesome arrhythmias.

**Specific Interrogation. PRECIPITATING FACTORS** Ventricular extrasystoles, heart block, ventricular tachycardia, and sinus tachycardia are common after myocardial infarction, sinus bradycardia, sinus tachycardia, and disturbances of conduction are often observed during or after diphtheria, influenza, pneumonia, mumps, or jaundice. Extrasystolic beats and paroxysms of supraventricular tachycardia may accompany gastrointestinal or emotional disorders.

**ONSET** The onset of arrhythmia is dramatically sudden or instantaneous in paroxysmal tachycardia (especially supraventricular), it is gradual in sinus tachycardia, and at times in ventricular tachycardia, in the last, it may be preceded by premature contractions.

**ASSOCIATED SYMPTOMS** An abnormal cardiac rhythm may be asymptomatic or may be associated with one or more symptoms. Palpitation is the most common symptom of all and is fre-

quently noted with extrasystoles, atrial fibrillation, paroxysmal tachycardia, and sinus tachycardia. A disagreeable thump or thud, when described after a pause, suggests a postextrasystolic beat. Episodes of convulsions, associated with loss of consciousness and cyanosis (Stokes-Adams attacks), are suggestive of AV block. Polyuria, or frequency during attacks, suggests paroxysmal tachycardia. Yawning, sighing, and a feeling of exhaustion are commonly associated with the sinus tachycardia of neurocirculatory asthenia and cardiac neurosis. A sense of fullness in the neck, occurring intermittently, is an uncommon manifestation of extrasystolic beats and is due to regurgitation of blood from the right atrium to the jugular veins. Dizziness or faintness may occur during attacks of paroxysmal tachycardia or "runs" of extrasystolic beats. Severe precordial pain may arise during a prolonged attack of paroxysmal tachycardia.

**TERMINATION OF ATTACK.** The termination of attacks is gradual in sinus rhythms and is usually sudden in paroxysmal supraventricular tachycardia. When an attack is stopped by stooping or bending down, holding of the breath, or mechanical stimulation of the vagus nerve, supraventricular paroxysmal tachycardia is likely.

**Pulsatory Phenomena. HEART RATE.** Since in

by auscultation at the apex, not at the wrist. Cardiac rates of below 40 beats per minute suggest either complete or severe incomplete AV block or nodal rhythm; regular rates of over 160 favor paroxysmal tachycardia. Sinus tachycardia and atrial flutter are usually associated with rates below 160 per minute. A persistent, regular, and unvarying cardiac rate of about 150 per minute, particularly in an elderly subject, suggests a 2:1 atrial flutter.

**PULSE DEFICIT** When the cardiac rate, determined at the apex, exceeds that of the radial pulse rate by 10 beats or more, a diagnosis of atrial fibrillation is justified. A pulse deficit, however, may also arise with ventricular extrasystoles, provided the pulses of the ectopic beats are too feeble to be conveyed to the radial pulse.

**JUGULAR PULSE.** Neck vein pulsations are of great diagnostic value, especially when studied in conjunction with the arterial pulse. For in-

Fig 6-10 A Fetal coarctation complex. A, ascending aorta; I, isthmus; D, ductus arteriosus; B, Patent ductus arteriosus. Usual type. ing a bidirectional shunt. It may, however, be an obliquely oriented foramen guarded by the septum primum acting as a valve. This type of opening becomes functional if the pressure in the right atrium exceeds that in the left. A

resultant pressure hypertrophy of the left ventricle. The hypertension is related not only to the resistance of the coarctation, but also to a renal factor. There is an anatomic subclinical type without hypertension.

INFANTILE TYPE. In this form, there is a diffuse narrowing of the isthmus of the aorta, which may involve the ostium of the left subclavian artery (short type) or the entire arch from the origin of the innominate (long type) (Fig 6-10A). Rarely, there may be complete absence of the arch. Associated with this, there is always a widely patent ductus arteriosus and right ventricular hypertrophy. The ascending aorta is smaller than normal, but not so small as the coarctated area (see Chap 1).

**Complexes Associated with Isolated Patent Ductus Arteriosus.** In the usual complex (Burchell, 1946; Gross and Longino, Gordon et al., Fig 6-10B), in long-standing cases, the right the left atrium and ventricle are hypertrophied left ventricle dominates. In a few cases, the right ventricle is dominantly or exclusively hypertrophied. All the above complexes may be associated with a mild coarctation, bicuspid aortic valve, or subaortic stenosis. All, likewise, show pulmonary arterial dilation with sclerotic changes in the pulmonary artery and valve.

**PATHOGENESIS OF THE COMPLEX.** In the usual case, there is a shunt from the aorta into the pulmonary artery, resulting in increased pulmonary flow. Hence, the left atrium and ventricle present a volume hypertrophy. Eventually, pulmonary vascular changes resulting in bidirectional or reversed flow. In a few cases, severe pulmonary hypertension occurs before puberty or shortly after birth, associated with reverse flow in the ductus. These cases are not well understood.

**Complexes Associated with Isolated Atrial Septal Defects (Blount et al., 1956; Dexters, Tauszig et al., 1938)** may be classified as (1) patent foramen ovale, (2) persistent ostium primum, and (3) defects in other parts of the atrial septum. A patent foramen ovale (Fig 6-11A) consists of an opening in the region of the fossa ovalis. When this opening is a direct communication between the atria, it represents a true functional atrial septal defect, permit-

small, nonfunctioning obliquely probe-patent foramen ovale is present in 20 to 25 per cent of normal hearts. A *persistent ostium primum* (Fig. 6-11B, C) consists of an opening in the lower part of the atrial septum, just proximal to the mitral and tricuspid valves. This opening is always of pathophysiologic importance.

In complexes associated with atrial septal defect, there is always right atrial and right ventricular hypertrophy and dilatation and dilatation of the pulmonary artery. The left atrium and ventricle are normal or small. This is the picture in the *secundum* type of defect. In the *primum* type of defect, there is usually a cleft anterior leaflet of the mitral and sometimes a cleft septal leaflet of the tricuspid. Here there may be left ventricular hypertrophy.

**PATHOGENESIS OF THE COMPLEXES** The right atrium and ventricle, in these complexes, present a volume hypertrophy. There is a markedly increased pulmonary flow. The left ventricle is small because of the left-to-right shunt at the atrial level. In the *primum* type of complex, there may be an associated mitral regurgitation, accounting for the left ventricle hypertrophy. When there is tricuspid regurgitation, there is an increased amount of volume hypertrophy of the right atrium and ventricle.

**Complexes Associated with Isolated Ventricular Septal Defect.** Isolated defects of the ventricular septum (Selzer, Wood et al.) are found mostly in the region of the *pars membranacea*, involving the adjacent anterior and posterior septa (Fig. 6-12). They may, however, also be found in the anterior or, uncommonly, in the posterior septum. These defects may be single or multiple. The complex created by this defect is dependent upon its size. When

small, the shunt is not large enough to produce hemodynamic effects. When large, the right ventricle is hypertrophied, and the left ventricle may or may not be hypertrophied. All such defects may have the following complications. (1) the aortic valve may be deformed or pulled down to produce aortic insufficiency; (2) the bundle of His may be involved by fibrosis to produce AV block; (3) the tricuspid valve may become adherent to the defect to produce tricuspid insufficiency, and (4) there may be superimposed bacterial endocarditis.

**PATHOGENESIS OF THE COMPLEX.** The right ventricle presents a volume and pressure hypertrophy, the shunt being from the left to the right ventricle. There is increased pulmonary flow and, hence, hypertrophy of the left atrium. The left ventricle is subjected to opposite influences. The increased volume leads to hypertrophy, while the decreased peripheral resistance leads to atrophy. Hence the left ventricle presents a variable picture. In general, in the early stages of the process, it is hypertrophied and in the latter stages, normal or atrophied.

**Complex Associated with Common Atrioventricular Orifice.** In this complex (Gunn and Dieckmann, Rogers and Edwards), there is one undivided AV orifice and one valve (Fig. 6-13A). This valve consists of an inferior leaflet on each side, and a common posterior leaflet made up of the medial leaflet of the tricuspid and the posterior portion of the anterior leaflet of the mitral, an anterior leaflet on the left side made up of the anterior half of the anterior leaflet of the mitral, and an anterior leaflet on the right side representing the true anterior tricuspid leaflet. The latter two may be fused

#### STUDY OF ARRHYTHMIAS

Nowhere, in the entire field of cardiology, has electrocardiography been exploited to greater advantage than in the interpretation of cardiac arrhythmia. The exact mechanism of many a hitherto obscure irregularity of the heart has been unraveled by resort to this method of instrumental investigation. Although the prime role of electrocardiography in the diagnosis of abnormal cardiac rhythms and its

unquestioned superiority over other methods of examination have been securely established in recent years, the informative value of a good history and thorough clinical examination in the understanding of cardiac arrhythmias has not been sufficiently appreciated. Since the subject of electrocardiographic interpretation of cardiac irregularities has been dealt with at great length in various chapters of Vol III of *Cardiology*, the present paper deals with the clinical differentiation only. The majority of cardiac arrhythmias, as a matter of fact, are clinically recognizable, provided a systematic method of cross examination or history taking and thorough physical examination are undertaken.

The following scheme of investigation, having proved valuable in the majority of cases, is recommended for routine adoption:

##### I. History

- A. General (age, sex, predisposing factors, etc.)
- B. Specific (regarding the various characteristics of the cardiac arrhythmia itself, e.g., onset, duration, associated symptoms, and cessation of attack)

##### II. Physical examination

- A. Observations of pulsatory phenomena
  1. Cardiac rate and rhythm
  2. Arterial pulse
  3. Venous pulsations
- B. Examination of the heart
  1. Presence or absence of organic heart disease
  2. Apex beat
  3. Heart sounds
- C. Special methods of clinical examination
  1. Effect of exercise
  2. Effect of deep respiration and of asphyxia
  3. Effect of carotid sinus pressure
  4. Levine's method

##### D. Examination of other systems

##### III. Instrumental investigation

- A. Fluoroscopy
- B. Electrocardiography
- C. Phonocardiography

**General Interrogation.** AGE. While certain arrhythmias, such as sinus arrhythmia, paroxysmal supraventricular tachycardia, and atrial extrasystoles, are common in the young, paroxysmal ventricular tachycardia, ventricular extrasystoles, and atrial flutter show a predilection for elderly subjects. Sinus arrhythmia is common in infants, children, and the aged. Attacks of supraventricular paroxysmal tachy-

breath may remove the irregularity of sinus arrhythmia, bring out latent extrasystoles, and help in the differentiation of pulsus paradoxus from pulsus alternans.

**CAROTID SINUS STIMULATION. COMPRESSION OF THE EYEBALLS.** These maneuvers have no effect on ventricular rate in complete heart block, atrial fibrillation, or ventricular tachycardia, they tend to cause further slowing of the heart rate in incomplete AV block, they frequently terminate an attack of paroxysmal supraventricular tachycardia, they bring about a gradual and transitory slowing of the heart rate in sinus tachycardia, they may cause a sudden halving of the rate in atrial flutter, even though, in most cases, they have only a moderate and temporary effect, particularly if there is variable block.

**LEVINE'S METHOD** "Tapping of the foot in rhythm with the heart" has been recommended by Levine as a useful method of differentiating supraventricular from ventricular tachycardia (even a slight irregularity of rhythm favoring the latter), atrial from ventricular extrasystoles (the postextrasystolic pause being strictly compensatory in the latter), SA from partial AV block (the pause, in the latter, does not correspond in length to two cardiac cycles), and atrial fibrillation from multiple extrasystoles (all pauses in the latter are preceded by small and rapid pulsations, i.e., premature beats).

**Instrumental Investigations. FLUOROSCOPY** Fluoroscopy may afford diagnostic clues in arrhythmias. Rapid and irregular undulations of the atria without proper contractions may be observed in atrial fibrillation. Synchronous contraction of the atria and ventricle, with additional contractions of the atria during the long diastolic pauses, is suggestive of AV block. In atrial flutter, rapid and regular contractions of the atria may be visible in the right anterior oblique position.

**ELECTROCARDIOGRAPHY** This method is capable of supplying information of immense diagnostic value and should be employed in every single case of cardiac arrhythmia; however, in many cases it serves only to confirm or exclude the diagnosis, after all clinical sources of information have been fully used.

### CLINICAL CLASSIFICATION OF CARDIAC ARRHYTHMIAS

The following eight types of cardiac arrhythmias are recognizable clinically, on the basis of rhythm,

rate, and perceptibility of cardiac pulsation (Vakil, 1954):

1. Regular rhythm with slow rate (rhythmic bradycardia)
2. Regular rhythm with rapid rate (rhythmic tachycardia)
3. Regular rhythm with normal rate
4. Regular rhythm with unequal force of beats
5. Irregular rhythm with slow rate (arrhythmic bradycardia)
6. Irregular rhythm with rapid rate (arrhythmic tachycardia)
7. Irregular rhythm with normal rate
8. Clinically silent (imperceptible) rhythm

**Type I: Regular Rhythm with Slow Rate** (1) Sinus bradycardia, (2) nodal rhythm, (3) incomplete (2:1 or 3:1) AV block, (4) complete AV block, (5) atrial flutter with 4:1 or 5:1 block, (6) atrial fibrillation with nodal rhythm.

A clinical diagnosis is possible, in the majority of cases, by simultaneous study of radial artery and jugular vein pulsations, and by palpation and auscultation of the heart.

**Type II: Regular Rhythm with Rapid Rate.** (1) Sinus tachycardia, (2) paroxysmal supraventricular tachycardia, (3) paroxysmal ventricular tachycardia, (4) 2:1 type of atrial flutter, (5) pre-excitation (Wolff-Parkinson-White) syndrome.

A clinical diagnosis is facilitated by paying attention to the following features: (a) past history of similar attacks, (b) mode of onset of arrhythmia, (c) mode of termination, (d) duration of attack, (e) rate of beating, (f) rhythm, (g) venous pulsations of the neck, (h) influence of exercise, respiration, carotid sinus pressure, and posture.

**Type III: Regular Rhythm with Normal Rate.** A regular rhythm with a normal rate of 70 to 80 beats per minute need not necessarily imply a normal sinus rhythm, as certain pathologic mechanisms are compatible with such a state. (1) first-degree AV block, with increased AV conduction time, (2) intra-atrial block, (3) intraventricular conduction defect, such as bundle branch block or arborization block, (4) paroxysmal tachycardia (usually supraventricular) with 2:1 block, (5) atrial flutter with 4:1 block, (6) nodal rhythm, when the cardiac rate is not unduly slow, (7) complete AV block (rarely) with unusually high idioventricular rate (e.g., congenital or diphtheritic), (8) sinus tachycardia, with alternating block (either SA or AV block).

Electrocardiography is usually essential for diagnosis of this group of cases.

**Type IV: Regular Rhythm with Unequal Force of Beats.** (1) Pulsus alternans, (2) pulsus paradoxus, (3) regularly alternating extrasystoles.

Clinical diagnosis is usually possible on the basis of "spacing" of the beats.

stance, in *sinus rhythm*, normal a, c, and v waves are seen, together with a characteristic systolic collapse of the jugular vein synchronous with each heart beat. On the other hand, in *nodal rhythm*, there is a large systolic pulsation or wave with each beat, because of simultaneous contraction of the right atrium and ventricle. In the *first-degree AV block*, with increased P-R interval, a characteristic delay occurs between the a and the c-v waves of the venous pulse; in *partial heart block*, a number of a waves are visible between the other waves and the degree of block can be determined by counting the ratio of a waves to radial pulses. In *complete heart block*, besides the phenomena of extra a waves, there are occasional large venous pulsations (familiarly known as "cannon waves"), owing to simultaneous contraction of atria and ventricles. In atrial fibrillation, even with slow rates, the absence of a waves reveals the diagnosis. In *atrial flutter*, typical, rapid, regular waves are visible during the diastolic pauses. Multiple and frequent *extrasystoles* can be differentiated from atrial fibrillation because the systolic collapse of the vein that occurs in the latter tends to decrease or disappear in the former.

**Examination of the Heart.** *Sinus bradycardia*, *sinus arrhythmia*, and *sinus tachycardia* are either physiologic or they are manifestations of cardiac or systemic disease. *Premature contractions* and *paroxysmal supraventricular tachycardia* are more often associated with normal hearts than with diseased ones. Diseases of the gastrointestinal and biliary tracts may induce reflex extrasystoles. *Paroxysmal ventricular tachycardia* seldom occurs except with severely damaged hearts. *Atrial fibrillation* may be connected with mitral stenosis, coronary sclerosis, or hyperthyroidism, in the latter case, fibrillation tends to be paroxysmal. In rheumatic fever, first-degree heart block is common and is of diagnostic significance. Diphtheria may cause a varying degree of AV block. Atrial flutter and heart block may be associated with congenital heart disease. A high systolic and a low diastolic pressure is usual in complete heart block.

**CHARACTER OF APEX BEAT.** Palpation of the cardiac apex may suggest the existence of bundle branch block in the event of a bifid or double thrust, and of *pulsus alternans* in the event of alternately vigorous and feeble pulsations. Detection of a displaced apex beat or thrill at the apex may indirectly suggest the nature of

the arrhythmia, by disclosing the presence or nature of organic heart disease.

**HEART SOUNDS.** The nature of an arrhythmia may be suggested by careful auscultation of the heart sounds, particularly at the apex. In *nodal rhythm*, the 1st sound tends to become louder each time that the atria and ventricle contract simultaneously. While in *paroxysmal atrial tachycardia*, the intensity of the 1st sound is constant from beat to beat, in *ventricular tachycardia* it may show a characteristic variation. In *atrial fibrillation* and *flutter* (particularly in the latter), the 1st sound tends to vary in intensity; in *atrial fibrillation*, the 2d sound may be absent, whenever the ventricular contraction fails to open the semilunar valves. In *atrial flutter*, extra sounds, due to audible atrial contractions, may be heard during diastole. In *first-degree AV block*, either the 1st sound becomes attenuated in intensity or an extra sound is heard in diastole because of early atrial contraction. In *second-degree AV block*, the 1st sound may be preceded by an atrial sound, a phenomenon never observed in SA block. In *complete AV block*, there is a slow but regular ventricular rate of 20 to 40 beats per minute, with variations in intensity of the 1st sound, which assumes at times a loud and explosive character, commonly referred to as *bruit de cannon*. Splitting of the 1st and 2d sounds may occur in *bundle branch block*; a diastolic triple rhythm in conjunction with *pulsus alternans* may also suggest this condition.

**Special Methods of Clinical Examination.**  
**EFFECT OF EXERCISE.** Acceleration of the pulse after exercise, atropine, or amyl nitrite, by its action on the cardiac arrhythmia, may supply information of diagnostic value. Although exercise tends to increase the cardiac rate in *sinus tachycardia*, it has no effect on the rate of *paroxysmal tachycardia*. The irregularity of the pulse in *atrial fibrillation* is usually accentuated by exercise. Exercise has little or no effect on the ventricular rate of *complete heart block*, but may cause the ventricular rhythm of the Wenckebach type of AV block to return to normal. In *atrial flutter*, the ventricular rate may be suddenly doubled by exercise, in *sinus rhythms*, the rise of rate tends to be gradual.

**EFFECT OF INSPIRATION.** Sustained and deep respiratory effort, whether inspiratory or expiratory, may terminate an attack of *supraventricular tachycardia* by stimulating the vagus nerve. The simple maneuver of holding the

## 11-120 (Supp.) RATE, RHYTHM, AND CONDUCTION DISTURBANCES

**Type V: Irregular Rhythm with Slow Rate (Arrhythmic Bradycardia).** (1) Sinus arrhythmia with sinus bradycardia, (2) sinus bradycardia with sinus pauses or SA block, (3) sinus bradycardia with extrasystoles (atrial, nodal, or ventricular), (4) nodal arrhythmia, (5) incomplete AV block with frequent dropped beats, (6) unstable AV block, (7) atrial flutter, with variable and high degree of block, (8) atrial fibrillation with slow ventricular response.

In the majority of cases, a clinical diagnosis is possible through careful interrogation and examination of the patient.

**Type VI: Irregular Rhythms with Rapid Rate (Arrhythmic Tachycardia).** (1) Atrial fibrillation, (2) atrial flutter, (3) sinus tachycardia with multiple extrasystoles, (4) AV dissociation (interference dissociation), (5) paroxysmal ventricular tachycardia.

Clinical diagnosis is usually facilitated by (a) artificially raising the cardiac rate with exercise, atropine, or amyl nitrate, (b) careful palpation of the pulse, for timing of beats, "pulse deficit," and "dominant rhythm"; (c) study of the 1st sound for variations in intensity.

**Type VII. Irregular Rhythm with Normal Rate.** (1) Sinus arrhythmia, (2) normal sinus rhythm with extrasystoles (atrial, nodal, or ventricular), (3) SA block, (4) sinus pauses, (5) partial AV block with irregular dropping of beats, (6)

Wenckebach type of AV block, (7) interference dissociation.

Clinical diagnosis is usually possible after a careful interrogation and examination of the patient.

**Type VIII. Clinically Silent (Imperceptible) Rhythms.** This group of arrhythmias is characterized by the complete absence, clinically, of all pulsatory phenomena, arterial, venous, and cardiac. (1) severe tachycardia (e.g., 1:1 atrial flutter), (2) ventricular flutter, (3) ventricular fibrillation, (4) paroxysmal tachycardia with ineffective systolic contractions (rare), (5) severe shock (e.g., after coronary thrombosis), (6) long sinus pauses or cardiac standstill (e.g., AV block with Stokes-Adams syndrome).

A careful study of symptoms and signs may furnish the required information, otherwise, an electrocardiogram is indicated for diagnosis.

## CONCLUSION

Despite the apparent complexity of cardiac arrhythmias, careful history taking, physical examination, and simple methods of clinical investigation often make it possible to recognize the nature of cardiac arrhythmias without having recourse to specialized methods of instrumental investigation, such as electrocardiography.

veins may thus drain into the systemic venous circuit. Such drainage is associated with one of the two following complexes

**PARTIAL ATRIAL SEPTAL DEFECTS** In this complex, either the right or the left pulmonary veins drain into the systemic veins or into the right atrium. Frequently, there is an associated atrial septal defect. The right atrium and ventricle are hypertrophied, and the pulmonary artery is dilated. The left side is normal. There may be an associated pulmonary or mitral stenosis.

**TOTAL ATRIAL SEPTAL DEFECTS** In this complex, all four pulmonary veins enter the systemic venous circuit (Fig. 6-18B, C). There is always a patent foramen ovale, and there is marked hypertrophy of the right atrium and ventricle. The pulmonary artery is large. The left side of the heart and aorta are small.

**TRANSPOSITION OF THE VENTRILES** The embryogenesis of the pulmonary veins has been described (see Chap. 1). The right atrium and ventricle present a volume hypertrophy, and the left atrium and ventricle a volume atrophy. **Complexes Associated with Congenital Pulmonary Stenosis and Normal Aortic Root.** In this complex (Campbell, 1934, Engle and Taussig), the pulmonary stenosis is usually

valvular (Fig. 6-18D). The pulmonary valve

into a bridging leaflet, or such bridging may occur between a cleft portion of the medial tricuspid and the anterior portion of the anterior mitral leaflet. There is always a combined septal defect consisting of a patent foramen ovale and a ventricular septal defect. The size of this defect varies markedly. The right atrium and ventricle are hypertrophied, and the pulmonary artery is large. The left side of the heart varies in size.

**TRANSPOSITION OF THE CORONARY VESSELS** The pathogenesis of the common AV orifice and the combined defect has been discussed in Chap. 1. The right atrium and ventricle present a volume and pressure hypertrophy. There is increased pulmonary flow. The size of the left ventricle varies according to the size of the atrial and ventricular septal defects, the amount of pulmonary flow, and the competence of the left side of the common valve.

**Complexes Associated with Anomalous Pulmonary Venous Drainage.** The usual method of such drainage is by way of the coronary sinus, the left innominate, or a persistent left superior vena cava (Brody, Gott et al., Uncommonly, the pulmonary veins drain directly into the right atrium. Less frequently, they may enter the right superior vena cava, the inferior vena cava, the portal vein, a pancreatic vein, or the ductus venosus. One, two, or all pulmonary

Fig. 6-12. Ventricular septal defect. A Left ventricular view. B, Right ventricular view.

is converted into a ringlike structure with a small opening, or less commonly, there is irregular thickening and adhesion between the cusps, producing a narrowing. The aorta arises in a normal position, and the architecture of the right ventricle is normal. The *crista supraventricularis* is hypertrophied but normal in architecture. There may be mild narrowing of the conus, or sometimes the primary stenosis is at the lower conal orifice. There is marked right ventricular hypertrophy and, in the later stage of the process, left atrial and left ventricular hypoplasia. The pulmonary stenosis may be

isolated or associated with an atrial or, less commonly, a ventricular septal defect.

**PATHOGENESIS OF THE COMPLEX.** The right ventricle presents a pressure hypertrophy. The size of the left side is normal, at an early stage, when there is normal pulmonary flow. In the later stages, with the onset of failure, pulmonary flow is diminished, hence the smallness of the left side.

**Complexes Associated with Isolated Congenital Supraaortic, Aortic, and Subaortic Stenosis** (Lev, 1954, Campbell and Kauntze; Mencarelli). The aortic outflow tract may be

Fig. 6-13. A. Common AV orifice. Right atrial and right ventricular view. Arrow points to the combined defect. B. Heart returned to position, showing entry of left superior vena cava into the innominate. In (B) and (C) C, confluence of pulmonary veins, L, left superior vena cava; I, innominate; R, right superior vena cava. C. Total pulmonary venous drainage into a partial left superior vena cava, which in turn drains into the innominate vein. Heart lifted upward to show the confluence of the pulmonary veins draining into the left superior vena cava. E. Isolated pulmonary stenosis. Right ventricular view. Arrow points to the stenosis (From M. Lev, *Autopsy Diagnosis of Congenitally Malformed Hearts*. Charles C Thomas, 1953.)

narrowed below the aortic orifice, at the aortic orifice, or at the upper margins of the sinuses of Valsalva (Fig 6-14A). In *subaortic stenosis*, there is a thickened ridge of endocardium and sometimes myocardium extending across the base of the ventricular septum, beneath the pars membranacea, up to and involving the aortic leaflet of the mitral valve. This usually produces a mild or moderate stenosis. In *aortic stenosis*, there is either a contraction of the aortic ring or a congenital deformity of the aortic valve with narrowing of the orifice. This valve may be *bicuspid*, with deformity of the cusps, or the entire valve may produce a ring, with no distinct division into cusps. In *supra-valvular aortic stenosis*, there is a contraction of the aorta at the upper margins of the sinuses of Valsalva. In all these complexes, there is left ventricular hypertrophy. In subaortic stenosis, there may be an associated bicuspid aortic valve and an aneurysm of a sinus of Valsalva.

**Complexes Associated with Isolated Aberrant Origin of a Coronary Artery from the Pulmonary Artery.** Either the left or the right coronary artery (Bland et al.; Gasul and Loeffler) may have an abnormal origin from the pulmonary artery (Fig 6-14C). It is not known whether both may originate from this vessel. Two different complexes therefore result

subendocardial fibrosis. Calcification of the myocardium may occur, and occasionally an infarct of the myocardium may be present.

**RIGHT CORONARY FROM THE PULMONARY.** There are no remarkable changes in the myocardium until adult life, when the patient may develop right ventricular failure.

**PATHOGENESIS OF THE COMPLEX.** When the left coronary artery originates from the pulmonary, there are ischemic hypertrophy and degenerative changes of the left ventricle. The effects upon the myocardium are related to the supply to the myocardium of blood with low oxygen content and under low pressure. When the right coronary artery originates from the pulmonary, there are lesser changes in the right ventricle, possibly related to a greater supply of blood through the thebesian circulation on the right side.

**Complexes Associated with Congenital Aneurysm of an Aortic Sinus of Valsalva.** Such aneurysms involve the right sinus of Valsalva

Fig 6-14 A. Supra-valvular aortic stenosis. Left ventricular view. B. Aneurysm of an aortic sinus of Valsalva. Arrow points to the aneurysm. C. Aberrant origin of left coronary artery from the pulmonary artery. Arrow points to the left coronary artery (From M. Lev. Autopsy Diagnosis of Congenitally Malformed Hearts. Charles C Thomas, 1953)

(Feldman et al.; Goehring) most frequently, less frequently the left or posterior sinuses, and rarely all sinuses (Fig. 6-14C). These may point toward or rupture into the right atrium, right ventricle, left atrium, left ventricle, pericardial sac, mediastinum, pulmonary artery, inferior vena cava, or left pleural cavity. Such an aneurysm may secondarily produce aortic insufficiency, tricuspid stenosis or insufficiency, conduction defects, or myocardial infarction secondary to compression of a coronary artery.

**Esophageal, Tracheal, and Bronchial Dislocation or Compression by Vessels.** Such dislocation or compression (Edwards, 1948; Ellis et al., 1955) most commonly is produced by (1) a double aortic arch (Fig. 6-15A), (2) origin of the right subclavian from the descending aorta, (3) a right aortic arch with a left descending aorta pulled over by a ductus arteriosus or a left subclavian. Rarely an anomalous left pulmonary artery may compress the right main bronchus.

**Complex Associated with Isolated Aortopulmonary Septal Defect.** An aortopulmonary septal defect (Downing; Kirklin et al., 1955) is a round or oval opening between the aorta and the pulmonary artery, situated usually just above the aortic valve (Fig. 6-15B). This leads to right ventricular hypertrophy, but both ventricles may be hypertrophied. The pulmonary artery is dilated, and secondary changes may occur at the pulmonic valve. The anomaly may be associated with a patent ductus arteriosus, patent foramen ovale, ventricular septal defect, or bicuspid aortic valve.

**PATHOGENESIS OF THE COMPLEX** The right ventricle presents a pressure hypertrophy due to pulmonary hypertension. The left ventricle may show a volume hypertrophy.

**Idiopathic Hypertrophy of the Heart with Fibroelastosis.** Here the entire heart is hypertrophied, or only the left ventricle. There is fibroelastosis (Wenberg and Himmelfarb, Johnson, 1952) of the left ventricle with or without involvement of the aortic and mitral valves. The left atrium and right ventricle may show similar changes. The cause of the hypertrophy is not apparent, unless it is the fibroelastosis.

**Bicuspid Aortic Valve.** A bicuspid aortic valve (Abbott, 1932; Gross, 1937) consists of either two distinct cusps or a distinct cusp and an undivided double cusp (Fig. 6-15C).

The latter presents itself as a single cusp with low raphe dividing. Usually the right and left are represented in the double cusp, less frequently the right and posterior, and least frequently the left and posterior.

A bicuspid aortic valve may be associated with no pathologic complex. It may, however, be associated with secondary hemodynamic or inflammatory change to produce an aortic stenosis.

**Cor Biatritium Triloculare, Cor Biloculare without Transposition, and Cor Triatriatum.** In *cor biatriatum triloculare*, only a vestige of the ventricular septum is present. The atrial septum and the mitral and tricuspid orifices are well formed. This condition may be associated with complete transposition as described above, or it may be present without it. In *cor biloculare*, only remnants of the atrial and ventricular septa are present, producing in effect a common AV orifice (Conn et al.; Mc-Lester et al.).

There are various forms of *cor triatriatum* (Pederson and Therkelson). In one form (*double left atrium*), a septum stretches across the left atrium, separating the opening of the pulmonary veins from the mitral orifice. There are thus two left atrial chambers, the right posterosuperior chamber receiving the pulmonary veins and the left anteroinferior chamber bearing the auricular appendage and communicating with the mitral orifice. The septum separating them usually has a defect. Where this septum is complete, the only exit from the pulmonary vein chamber is a channel draining wholly into the superior vena cava. With this anomaly, there is right atrial and right ventricular hypertrophy, dilated pulmonary artery, and small left ventricle. The dynamics here are similar to those of mitral stenosis.

In a second type of *cor triatriatum*, the pulmonary veins enter the left, the superior vena cava the middle, and the inferior vena cava the right atrium. In a third variation, the pulmonary veins enter the left and the normal superior and inferior venae cavae the right. A third chamber lies between the septum primum and secundum receiving the left superior vena cava, entering the coronary sinus.

**Dextrocardial Complexes.** In *dextrocardia* and *dextroversion* (Lev, 1953; Lichtman), the apex-base axis points toward the right and downward (Fig. 6-16). In *dextroversion*, this

is due to extraneous pathologic changes shifting or rotating the heart. In dextrocardia, the position is due to inherent structure of the heart itself. There are three types of dextrocardia, depending upon the position of chambers. (1) mirror-image dextrocardia, (2) pivotal dextrocardia, and (3) mixed dextrocardia.

In mirror-image dextrocardia, the morphologically left atrium and ventricle are situated posteriorly and to the right, while the morphologically right atrium and ventricle are situated anteriorly and to the left. This type of dextrocardia may be associated with generalized situs inversus, or it may be isolated.

Fig 6-15 A Double aortic arch A, ascending aorta; L, left aortic arch; R, right aortic arch, D, descending aorta, T, trachea, E, esophagus B Aortopulmonary septal defect Small white rod passes through the defect, C Bicuspid aortic valve (B C From M. Lev. Autopsy Diagnosis of Congenitally Malformed Hearts Charles C Thomas, 1953)

When it is the former, there is usually no congenital heart disease. In the latter, a true congenital heart disease exists, with all the complexes seen in levocardia being found in dextrocardia. In pivotal dextrocardia, the position of chambers is such as would be obtained if the heart in pure levocardia were rotated anteriorly and to the right in a horizontal plane. Thus, the morphologically left atrium and ventricle are situated anteriorly and to the left, while the morphologically right atrium and ventricle are situated posteriorly and to the right. This type of dextrocardia is always found in the isolated form, and most cases of isolated dextrocardia are of this type. They are always associated with congenital heart disease, and all types of such disease found in levocardia may be found here. In mixed dextrocardia, the atria and ventricles do not correspond. Thus the atria may be in pivotal position and the ventricles in mirror image, or vice versa. Again any type of complex malformation may accompany this arrangement of chambers.

The combination of dextrocardia, hypertrophic rhinitis, nasal polyposis, sinusitis, and bronchiectasis is called *Kartagener's disease*.

**Isolated Levocardia.** The apex-base axis of the normal heart points to the left and down and may be said to be in a state of levocardia. When this position is obtained in association with transposition of the abdominal viscera (Campbell and Forgacs), there is an isolated

levocardia. There are two basic complexes associated with this position. In one, the superior vena cava is on the left side and the heart chambers are transposed, with a right aortic arch. Some form of transposition of the arterial trunks, ventricular septal defects, and pulmonary stenosis are often associated. In the second type, the superior vena cava is on the right side and the chambers are in normal position. Here, there is defective septation of atria and ventricles, with transposition of the arteries and abnormalities in systemic and sometimes venous return.

**Mixed Levocardia.** In this condition (Lev, 1953) the base-apex axis points toward the left and down, but the atria and ventricles do not correspond (Fig. 6-17A). Sometimes the atria and sometimes the ventricles are transposed. This position of the chambers may be associated with any type of congenital heart disease.

**Rare Complexes.** In congenital idiopathic dilatation of the pulmonary artery, the pulmonary artery is large, the aorta small, and the right ventricle may or may not be hypertrophied. The right ventricular pressure is normal, but there is a drop in pressure in the pulmonary artery. In isolated congenital mitral stenosis, a deformed mitral valve is present without any deformity of the aortic valve. Rarely there is combined stenosis of the aortic and pulmonic valves. In congenital tricuspid insufficiency, the valve may consist of two

leaflets, an anterior and a fused posteroseptal, both attached to the septal wall by short slender chordae, or the chordae may be connected to small rudimentary papillary muscles. In premature closure of the foramen ovale, this opening is closed at birth. There is an associated small left atrium and ventricle and enlarged right side.

#### Complexes Associated with Other Diseases.

In *Marfan's syndrome* (McKusick), the most common associated cardiac complex is aneurysmal dilatation of the ascending aorta, aneurysms of the sinuses of Valsalva, dilatation of the aortic ring with regurgitation, and upward displacement of the coronary ostia. Another common complex is mild coarctation of the aorta, dilatation of the ascending aorta, aneurysms of the sinuses of Valsalva, with or without a left superior vena cava. Both complexes may end in dissecting aneurysm. In some cases, there is idiopathic dilatation of the pulmonary artery, an atrial septal defect, a patent ductus arteriosus, a tetralogy of Fallot, congenital mitral insufficiency, pectus excavatum, kyphoscoliosis, or conduction disturbances. In *pectus excavatum*, the heart is displaced to the left and upward and is flattened in the anterior and the posterior diameters.

In *gargoylism* (*lipochondrodystrophy*) (Emanuel), there is thickening and nodularity of the mitral, aortic, tricuspid, and pulmonic valves in order of occurrence, associated with thickening of the ventricular endocardium and chordae. The right atrium and ventricle are hypertrophied, and the pulmonary artery is large.

*Malignant carcinoids* (Branwood et al.) may be associated with fibrosis and thickening of the endocardium of the right ventricle with involvement of the pulmonary or the tricuspid valves, or both, with resultant pulmonary stenosis, with or without tricuspid stenosis or insufficiency.

*Agensis of the spleen* (Ivemark) is associated with common AV orifice, persistent ostium primum, pulmonary stenosis or atresia, dextrocardia, transposition complexes, anomalous pulmonary venous drainage, and right aortic arch. In *glycogen storage disease*, the heart may be diffusely hypertrophied, with glycogen infiltration of the sarcoplasm of the myocardial fibers.

Fig 6-17. A Mixed levocardia. Right atrial and left ventricular view C, coronary sinus, 1, inferior vena cava B. Rete Chiani C Double mitral orifice. Arrow points to accessory mitral orifice (B From Lev. Autopsy Diagnosis of Congenitally Malformed Hearts Charles C Thomas, 1953)

When it is the former, there is usually no congenital heart disease. In the latter, a true congenital heart disease exists, with all the complexes seen in levocardia being found in dextrocardia. In pivotal dextrocardia, the position of chambers is such as would be obtained if the heart in pure levocardia were rotated anteriorly and to the right in a horizontal plane. Thus, the morphologically left atrium and ventricle are situated anteriorly and to the left, while the morphologically right atrium and ventricle are situated posteriorly and to the right. This type of dextrocardia is always found in the isolated form, and most cases of isolated dextrocardia are of this type. They are always associated with congenital heart disease, and all types of such disease found in levocardia may be found here. In mixed dextrocardia, the atria and ventricles do not correspond. Thus the atria may be in pivotal position and the ventricles in mirror image, or vice versa. Again any type of complex malformation may accompany this arrangement of chambers.

The combination of dextrocardia, hypertrophic rhinitis, nasal polyposis, sinusitis, and bronchiectasis is called *Kartagener's disease*.

**Isolated Levocardia.** The apex-base axis of the normal heart points to the left and down and may be said to be in a state of levocardia. When this position is obtained in association with transposition of the abdominal viscera (Campbell and Forgacs), there is an isolated

levocardia. There are two basic complexes associated with this position. In one, the superior vena cava is on the left side and the heart chambers are transposed, with a right aortic arch. Some form of transposition of the arterial trunks, ventricular septal defects, and pulmonary stenosis are often associated. In the second type, the superior vena cava is on the right side and the chambers are in normal position. Here, there is defective septation of atria and ventricles, with transposition of the arteries and abnormalities in systemic and sometimes venous return.

**Mixed Levocardia.** In this condition (Lev, 1953) the base-apex axis points toward the left and down, but the atria and ventricles do not correspond (Fig. 6-17A). Sometimes the atria and sometimes the ventricles are transposed. This position of the chambers may be associated with any type of congenital heart disease.

**Rare Complexes.** In *congenital idiopathic dilatation of the pulmonary artery*, the pulmonary artery is large, the aorta small, and the right ventricle may or may not be hypertrophied. The right ventricular pressure is normal, but there is a drop in pressure in the pulmonary artery. In *isolated congenital mitral stenosis*, a deformed mitral valve is present without any deformity of the aortic valve. Rarely there is *combined stenosis of the aortic and pulmonic valves*. In *congenital tricuspid insufficiency*, the valve may consist of two

and valvular opening supplied with its own leaflets, chordae, and papillary muscles, lying within the segments of an otherwise normal orifice, or there may be two orifices lying side by side of equal or unequal thickness. In double mitral orifice (Fig 6-17C), the accessory (usually smaller) orifice may lie in the anterior or inferior mitral leaflet, having two leaflets of its own joined to the anterior or inferior papillary muscles. In some cases, each orifice has one leaflet, with the two orifices joined by a fibrous tissue ridge.

**BICUSPID AND IRREGULARLY FORMED PULMONIC VALVE.** This valve may consist of two well-approximated cusps, or the cusps may be small and insufficient. At times, a portion of the wall may be uncovered by cusp tissue. This is usually associated with transposition or tricuspid atresia complexes. Rarely it may be an isolated anomaly.

**ACCESSORY PULMONARY ARTERIES.** Such arteries may arise from the thoracic or abdominal aorta or from the seventh intercostal artery. They may supply accessory lobes of the lung or the normal lung.

**CONGENITAL ANEURYSM OF THE PULMONARY ARTERY.** This usually involves the main trunk alone, but the entire secondary branches may also be involved. It may be related to Marfan's syndrome or abnormally formed pulmonic valves.

**ABSENT DUCTUS ARTERIOSUS.** If the pulmonary arterial trunk and the two pulmonary arteries fail to develop, then the ductus arteriosus is also absent.

**BILATERAL DUCTUS ARTERIOSUS.** These may be connected to both the right and left pulmonary arteries, where there are complex malformations of the aortic arches.

**ANEURYSM OF THE DUCTUS ARTERIOSUS.** This is a rare entity.

**ABNORMAL CHORDAE.** Chordae, bands, or reticula may be found in any chamber.

**CONGENITAL DIVERTICULUM OF THE LEFT VENTRICLE.** Here there is an outpouching of the heart lined by smooth, thickened endocardium, and whose wall consists of all three layers of the heart.

**SUPERNUMERARY AND FENESTRATED SEMILUNAR CUSPS.** The aortic and pulmonic valves may have four, five, or more cusps. Fenestrated cusps are commonly seen in the aortic valve and less commonly in the pulmonic valve. It is not known whether they are congenital.

**ANOMALIES OF THE CORONARY ARTERIES ARISING FROM THE AORTA.** There may be a single coronary artery arising from the aorta. This vessel may follow the course of the left or right coronary or neither, or it may divide into the normal left and right coronary arteries. Rarely, a coronary artery may supply the lung or anastomose with pulmonary branches. Rarely, a coronary artery may communicate with the right ventricle.

**RIGHT AORTIC ARCH.** There are two types of right aortic arch. (1) In one type, the aorta ascends toward the right, arches over the right bronchus, and descends over the right side of the vertebral column. The brachiocephalic vessels are given off in mirror image. This is called simply *right aortic arch*. (2) In the second type, after arching over the right bronchus, the vessel deviates toward the left of the vertebral column, but still somewhat to the right of the position of the normal aorta. This is *right aortic arch with left descending aorta*. This is usually obtained by a *left-sided ductus* or left subclavian pulling the *right aortic arch* to the left.

**OTHER ABNORMALITIES OF THE BRACHIOCEPHALIC VESSELS.** All the brachiocephalic vessels may arise as one from the aorta. More commonly, the innominate and left common carotid may arise as one. The left subclavian artery may originate from the aorta distal, at, or from the ductus arteriosus.

**Congenital Glycogenic Tumors (Rhabdomyomas).** These tumors (Lev) are most commonly found in the left ventricle. They may be single or multiple. Generally, they are yellowish-white in color, homogeneous, and soft in consistency. Microscopically they consist of large, vacuolated muscle cells containing glycogen. Associated with these tumors, there may be cysts or tumors of the kidneys, tumors of sebaceous glands, harelip, cleft palate, gliomas of the brain, and other congenital malformations of the pancreas, kidneys, and lungs.

**Congenital Atrioventricular Block.** This is associated with an interruptive lesion in the pre-AV nodal area, the AV node, or the bundle (Campbell and Thorne). Such lesions have been found in ventricular septal defect, patent foramen primum, and mixed levocardia and have been postulated in many other conditions.

**Wolf-Parkinson-White Syndrome.** This may be found in Ebstein's disease, ventricular septal defects, or coarctation of the aorta (Lev et al.) This electrocardiographic abnormality may also be present without gross congenital malformations. Aberrant muscular communications between the right atrium and right ventricle, the AV node and the ventricular musculature, or the left atrium and ventricle may be found in the syndrome.

**Incidental Malformations.** In addition to the above malformations, which are best discussed as forming complexes, there are many other abnormalities which are incidental findings with little or no effect upon the heart (Lev, 1953, Abbott, 1927; Edwards, 1953).

**DEFECTS OF THE PERICARDIUM** These may be present on the anterior and left aspects of the heart, producing continuity between the pericardial sac and the left pleural cavity. Occasionally, there is a localized defect in the region of the pulmonary artery. The pericardium may be found unattached to the central tendon of the diaphragm. The right pericardial wall may be attached to the chest wall.

**DIVERTICULUM OF THE PERICARDIUM.** Such a formation may be found at the base of the aorta, or at the junction of the superior and inferior venae cavae on the right side, or at the junction of the pulmonary veins on the left side. This communicates with the main pericardial cavity by a small opening, which may close, producing a cyst.

**ECTOPIA CORDIS.** The heart may be displaced outside the thoracic cavity being (1) cervical, (2) thoracic with a fissure of the sternum, (3) abdominal with a defect of the diaphragm, or (4) thoracoabdominal. The myocardium may be completely exposed or covered by skin and subcutaneous tissue. Ectopia cordis is usually associated with complex malformations of the heart and with skeletal abnormalities.

**BIFID APEX.** Here there are two apices, one for the left and the other for the right ventricle. Where present alone, it is familial and hereditary.

**DOUBLE AND LEFT CORONARY SINUS.** Where the mouths of the coronary veins enter the left atrium, there is a blind sac for the entry of the coronary sinus into the right atrium. The coronary veins may drain into two sinuses, each entering a single atrium.

**PERSISTENT LEFT SUPERIOR VENA CAVA.** A left superior vena cava may be present together with a right superior vena cava, with or without a communication between them, or a left superior vena cava may be the sole venous brachiocephalic drainage. The latter usually enters the coronary sinus, less frequently the right atrium directly, the left atrium or both atria.

**ABNORMAL RIGHT SUPERIOR VENA CAVA.** This may enter the left atrium or it may straddle the atrial septum to enter both atria.

**ABSENT INFERIOR VENA CAVA.** The upper part of the inferior vena cava is absent, the hepatic veins entering the heart directly. The azygos veins drain the lower extremities.

**RETE CORDARI.** This consists of a network of fine endocardial fibers, extending from the eustachian and thebesian valves to the linea terminalis (Fig 6-17B). This may be the seat of thrombosis.

**ABNORMAL EUSTACHIAN AND THEBESIAN VALVES.** Either may be absent, enlarged, or fenestrated. They may be represented by a common valve.

**ANEURYSMAL DILATATION OF THE FOSSA OVALIS.** The atrial septum in the region of the fossa ovalis may be outpouched in either direction. The limbus usually has a wide arc, and part of it may be included in the aneurysm.

**DOUBLE TRICUSPID AND MITRAL ORIFICES.** In double tricuspid orifice, there may be a sec-

Bacterial endocarditis, arteriosclerotic valve changes, 8-5

arteriosclerotic valvulitis, 8-5

arteriovenous aneurysm, 8-12

Aschoff bodies, 8-11

atrial fibrillation, 8-6

bacitracin in treatment of, 8-15

bacteremia, 8-4

bacteria precipitate and grow on valve surfaces, 7-26

bacteria through blood channels within valve, 7-26

bacterial implantation, 8-4

bactericidal agents for combating, 8-16

bacteriology, 8-7 to 8-10

bacteriostatic agents for combating, 8-16

Benemid in treatment of, 8-15

bicuspid aortic valve the underlying pathology, 8-5

blood cultures, Becton-Dickinson prepared media, 8-9

blood taken from arteries, 8-8

epinephrine used, 8-8

importance of technique, 8-8

Kracke's medium, 8-9

Sabouraud's medium, 8-9

withholding of antibiotics, 8-8

cardiac infarction, 8-5

cause of death in rheumatic heart disease, 7-25

caused by micrococcus, 8-17

congenital heart disease, 8-5

congestive heart failure, mortality rates, 8-12

criteria for success of therapy, 8-18, 8-19

cultures of bone marrow, 8-8

deformity of valve following, 8-10

diagnosis of, 8-12, 8-13

effect of age on, 8-6

effect of stress on, 8-6

effect of, on central nervous system, 8-11

on kidney, 8-11

on pulmonary artery, 8-3

on spleen, 8-11

embolic myocardial lesions following, 8-10

embolic phenomena, 8-10

enterococcus, 8-14

erythromycin in treatment of, 8-15

exfoliative dermatitis from penicillin, 8-16

follow-up, 8-19

followed by hypertensive cardiovascular disease, 8-11

following acute sepsis, 8-5

following cardiac catheterization, 8-4

following surgical operation within the heart, 8-4

frable nature of surface lesions, 8-10

fungi as causative organism, 8-3, 8-7

glomerulonephritis, diffuse, 8-11

history of, 8-4

Bacterial endocarditis, host resistance, 8-4, 8-7

hypersensitivity reaction, 8-10

implantation of bacteria, 8-4 to 8-7

interventricular septal defect the underlying pathology, 8-5

Janeway lesions, 8-11

limited coronary blood flow, 8-5

meningitis, 8-11

microorganisms found in, 8-7

mixed organisms, 8-8

mucous membrane lesions, 8-11

mycotic aneurysm, 8-11

myocardial infarction, 8-10

myocarditis, 8-64, 8-85

Osler's nodes, 8-11

pathogenesis of, 8-4 to 8-7

pathology, 8-10 to 8-12

penicillin in treatment of, 8-13

petechiae, 8-11

phenoxymethyl penicillin in treatment of, 8-16

potassium penicillin G, 8-14

pregnancy, 8-4

probenecid, 8-15

to combat micrococcus, 8-17

prognosis, immediate, 8-19

long-range, 8-19, 8-20

prophylaxis, 8-20

puerperium, 8-4

repeated injections of bacteria experimentally, 8-6

role of trauma and stress, 7-26

skin lesion, 8-11

sodium penicillin G, 8-15

splinter hemorrhages, 8-11

*Streptococcus salivarius*, 8-14, 8-15

*Streptococcus viridans*, 8-4

streptomycin in treatment of, 8-15

subendocardial hyalinization, 8-5

superimposed on already damaged heart, 8-5

surgery of mitral insufficiency, 7-131

sypilis, 8-5

aortic insufficiency, 8-10, 8-17

treatment, continuous intravenous drip method for penicillin, 8-15

drug must penetrate fibrin, 8-13

historical, 8-13, 8-14

long-acting preparations of penicillin, 8-14

modern concepts of, 8-14 to 8-10

tuberculosis, 8-12

typhoid fever, 8-12

undulant fever, 8-12

upper respiratory infections, 8-4

Bacterial implantation, bacterial endocarditis, 8-4

Ballistocardiography, coronary heart disease, 10-40

pericarditis, 8-33

adhesive and constrictive, 8-49

Bands of Sturtz, adhesive and constrictive pericarditis, 8-47

Barbiturates, surgery of mitral stenosis, 7-126

# Index

Abnormalities, complete transposition, 6-10, 6-11  
partial transposition, 6-10  
pathogenesis of, 6-10 to 6-14

pericarditis, 8-26

Acetylcholine, in open intracardiac surgery, 6-189  
supraventricular tachycardia, 11-15  
used in cardiac arrest, 6-174

Aconitine, cause of ventricular flutter and fibrillation, 11-40

ACTH, in disseminated lupus erythematosus, 8-41  
in pericarditis, 8-41  
in rheumatic fever, 7-42

Acylamid, supraventricular tachycardia, 11-15

Acynotic diseases, types of, 5-6

Adhesive pericarditis (*see* Pericarditis, adhesive)

Adolescents, rheumatic heart disease, prevalence of, 5-10

Adrenocorticotrophic hormone (*see* ACTH)

Age, effect, on bacterial endocarditis, 8-8

on coronary circulation, 10-10

on death rates, 5-9, 5-10

on mitral stenosis surgery, 7-123

on myocardial infarction, 10-24

relationship to rheumatic fever, 7-30

upper limits of normal P-R intervals, 7-35

Agencies, angiocardiology, 6-162

of the spleen, 6-33

Ambulation, graduated, in rheumatic fever, 7-41

Aminophyllin, coronary heart disease, 10-48

myocardial infarction, 10-51

Amyl nitrite, coronary heart disease, 10-48

inhalation of, for sinus bradycardia, 11-5

parathrymia, parasympole, 11-105

Amyloidosis, myocarditis, 8-81

Anacrotic notch, valvular stenosis, 6-98, 6-99

Anacrotic shoulder, valvular stenosis, 7-62

Anaphylactic shock, eclimococcus disease, 8-96

Anastomosis, stenosis, 10-22

Anatomic classification of congenital heart disease, 6-37

physiologic interpretation, 6-38

Anatomy of coronary heart disease, 10-8 to 10-12

Anemia in adhesive and constrictive pericarditis, 8-45

Anesthesia in surgery of mitral stenosis, 7-125

Aneurysm, aortic (*see* Aortic aneurysm)

arterial, hydatid, 8-95

arteriovenous, bacterial endocarditis, 8-12

ventricular (*see* Ventricular aneurysm)

Angina pectoris, disuse of term, 10-30

Angiocardiogram, atrial myxoma, right, 6-167

Ebstein's anomaly, 6-158

hypertension, mild, of upper extremities with

hypotension of lower extremities, 8-150

pulmonary arteriovenous fistula, 6-164

pulmonary artery, right, congenital absence of, 6-163

pulmonary vein, right, anomalous drainage of, 6-165

pulmonic stenosis, isolated valvular, 6-153

stenosis of right pulmonary artery, 6-154

transposition of great vessels, complete, 6-160

tricuspid atresia, with pulmonary stenosis, 6-161

tricuspid stenosis, 6-167

vena cava, superior, bilateral, 6-166

Angiocardiography, aorta, 6-164 to 6-167

dextroposition of, 6-159

overriding of, 6-159

aortic arch, right, 6-159

aortic septal defect, 6-157

aortic sinus, aneurysms with associated anomalies, 6-167

unperforated aneurysms, 6-164

aortic stenosis, 6-152

with coarctation of aorta or patent ductus arteriosus, 6-159

arterial vessels, large, anomalies of, 6-162 to 6-164

atrial myxoma, 6-168

atrial septal defect, 6-155

coarctation of aorta, 6-155

combined malformations, 6-157 to 6-159

complex malformations, 6-159 to 6-162

congenital heart disease, 6-152 to 6-168

coronary arteriovenous fistulas, 6-168

coronary artery, anomalies of, 6-168

Eisenmenger's complex, 6-160

lung, absence of, 6-163

- Cardiac catheterization, intracardiac variations in blood oxygen content, 6-116 to 6-118

sis and significance of alterations of the pulmonary vascular bed were questioned. Anatomic vascular alterations have been described in an ever-increasing number of diseases, both

cardiac and pulmonary. These alterations may be primary, but more likely they result from the underlying cardiac or pulmonary disease; their presence, however, may significantly ef-

### ANATOMIC CLASSIFICATION OF CONGENITAL HEART DISEASE

Group I Defects between great vessels or ventricles with or without pulmonary stenosis

#### A Simple defects

1. Patent ductus arteriosus
2. Aortic septal defect
3. Single ventricle
4. Ventricular septal defect
5. Truncus arteriosus

#### B Complicated defects

1. Ruptured sinus of Valsalva into right ventricle
2. Coarctation of the aorta distal to a patent ductus
3. Coarctation of the aorta proximal to a patent ductus
4. Single ventricle with transposition of great vessels
5. Atrioventricularis communis
6. Biloculate heart
7. Tricuspid atresia
8. Tricuspid atresia with transposition
9. Corrected transposition of great vessels with ventricular defect
10. Transposition of the great vessels with
  - a. Patent ductus arteriosus
  - b. Ventricular defect
11. Taussig-Bing syndrome

#### C Complicated defects associated with conditions causing an elevated pulmonary venous pressure

1. Aortic atresia with patent ductus arteriosus and small patent foramen ovale
2. Aortic and mitral atresia with patent ductus arteriosus and small patent foramen ovale
3. Mitral atresia with ventricular defect and small patent foramen ovale
4. Mitral stenosis with closed foramen ovale and
  - a. Patent ductus arteriosus
  - b. Ventricular defect

Group II Defects between atria with or without pulmonary stenosis

#### A Simple defects

1. Secundum defect

#### B Complicated defects

1. Mitral stenosis with large atrial septal defect (if ...)
2. ...
3. ... with atrial septal defect

4. Ebstein's disease with patent foramen ovale

#### C Complicated defects associated with mitral insufficiency

1. Primum defect with cleft mitral valve
2. Secundum defect with mitral insufficiency (e.g., short chordae)

#### D. Complicated defects associated with pulmonary venous obstruction

1. Mitral stenosis with small patent foramen ovale

Group III Defects of pulmonary venous drainage

1. Partial return to right atrium with or without patent foramen ovale

2. Total anomalous venous return with patent foramen ovale

a. ...

b

c

d. no coronary sinus

3. Total anomalous and obstructed venous return to portal system with patent foramen ovale

Group IV. Lesions not associated with a communication

#### A Left-sided lesions

1. Coarctation of the aorta

2. Aortic stenosis

3. ...

4

5

... artery

B Left-sided lesions always associated with elevated pulmonary venous pressure

1. Congenital mitral stenosis

2. Triad of mitral stenosis, bicuspid aortic valve, and coarctation of the aorta

3. Ebstein's disease of the mitral valve

4. Congenital pulmonary venous obstruction

5. Congenital mitral insufficiency

#### C Right-sided lesions

1. Primary pulmonary vascular disease (primary pulmonary hypertension)

2. Coarctation of the pulmonary arteries

3. Valvular pulmonary stenosis

4. Pure infundibular pulmonary stenosis

5. Tricuspid stenosis

6. Ebstein's disease with closed foramen ovale

# *Clinical aspects of congenital heart disease*

J. FRANCIS DAMMANN, JR.

## INTRODUCTION

In the formative years of a new medical discipline, diagnosis and treatment tend to be oversimplified and the emphasis is placed upon the obvious manifestations of a disease process. The boundaries are determined in this way, and an understanding and treatment of the classical syndrome evolves. It is only later that appreciation emerges of the subtle distinctions that alone may separate one condition from another. So it is with the field of congenital heart disease. Led by Dr. Maude Abbott, a determined effort was made to subdivide cardiac malformations in a reasonable way by carefully analyzing the classical syndrome and correlating clinical findings with the exact anatomic abnormality. That this approach was successful cannot be denied, for rapidly there followed specific therapy for certain malformations. However, this approach is limited because it is based primarily upon an analysis of the anatomic variations (see the accompanying classification). Abbott, recognizing that progressive changes could occur, developed a classification which took into account alterations in hemodynamics. In her analysis of the group of patients with cyanosis tardive in which a reversal of shunt occurs, she implies that a sound classification of congenital heart disease must be based on physiology as well as anatomy.

In the present-day approach to congenital cardiovascular disease, the role of the sys-

temic and pulmonary circulation has achieved greater recognition as a determining factor in the clinical manifestations of a particular malformation of the heart. Classifications of congenital heart disease are now concerned more with physiology than with anatomy. We appreciate fully that congenital heart disease is not static; we realize that the full implications of the natural history of the disease must be understood. It is only in this way that the optimal results from therapy can be obtained since it is necessary to know not only the exact anatomy, but the ideal time for surgical intervention.

In this chapter, an attempt will be made to integrate the pulmonary circulation with a particular malformation and to point out the clinical signs and symptoms which result from changes in the pulmonary vascular bed. Therefore, before discussing the individual defects, it would be well to consider in general terms those factors in the pulmonary circulation which alter the clinical picture produced by cardiac anomalies. On this basis, a physiologic classification of congenital heart disease is presented (Table 6-1), and each malformation will be discussed within the framework of this classification.

The important role of the lungs in shaping the clinical course of patients with heart disease has only recently been recognized. Respiratory function was the first to be studied. The importance of the pulmonary circulation received recognition only when the pathogene-

electrolymographic findings, 6-101

overriding aorta with aortic hypoplasia, 6-17 to  
6-19

with tricuspid insufficiency, EKG tracings of,  
6-102

types of, 5-7

Eisenmenger's syndrome, 6-54

bundle branch block, complete right, 11-77

congenital heart disease with cyanosis, 6-106

effect of repeated venesections on, 6-108

Eisenmenger type, 6-20

Electric stimulation, external, in cardiac resuscita-  
tion, 11-107 to 11-114

Electrocardiogram, accuracy of response of re-  
cording system, 6-88

aortic valvular stenosis, 7-74

bundle branch block, incomplete left, 11-81

left and right, 11-79

with myocardial infarction, 11-83

Electrocardiogram, congenital heart disease, 6-15,  
6-46, 6-85 to 6-88

coronary artery, does not record changes in,  
10-84

coronary heart disease, atypical, 10-73

during cardiac catheterization, 7-72

echinococcus disease, 8-97

electrical amplification, 6-88

infarction, anterior followed by posterior, 10-76

anteroseptal, 10-63

high lateral, 10-69

posterior, 10-71

left ventricle, aneurysm of, 10-77

left ventricular preponderance in adults, 6-45

mitral commissurotomy, 7-72

mitral stenosis, 7-71

myocardial infarction, 10-68, 10-70, 10-73, 10-74

paroxysmal, AV dissociation, 11-101 to 11-103

paroxysm, 11-105

paroxysmal tachycardia, 11-91

pericarditis, 8-37

7-68

.....  
.....  
.....  
.....  
.....

change in pattern of QRS, 7-68

rheumatic myocarditis, 7-69

right axis deviation in newborn, 6-45

right ventricular preponderance in newborn,  
6-45

rudimentary preexcitation, 11-92

serial ECGs, 6-45

simultaneous lead system, 6-88

sinus arrhythmia, 11-4

sinus bradycardia, 11-4

sinus tachycardia, 11-3

supraventricular tachycardia, 11-11, 11-18

surgery, mitral insufficiency, 7-134

ventricular tachycardia, 11-19 to 11-21

Electrocardiographic examination for early detec-  
tion of heart diseases, 5-17

Electrocardiography, atrial fibrillation, 11-35, 11-38

complete left, 11-77 to 11-79

complete right, 11-74 to 11-77

complete AV block, 11-49

coronary heart disease, 10-42, 10-43, 10-64 to  
10-73

correlation with electrolymographic findings,  
10-86 to 10-90

differential diagnosis, 10-75 to 10-79

hypertrophy of right ventricle, 10-75

pericarditis, 10-78

coronary sclerosis, 10-64

digitalis, effect of, 10-76

echinococcus disease, 8-95, 8-96

exercise test, 10-66

infarct, location of, 10-72, 10-73

## Electrocardiography, infarction, acute subendocardial, 10-71

posterior wall of heart, 10-71

influenza, 8-86, 8-87

mitral insufficiency, 7-72, 7-73

myocardial infarction, coronary heart disease, 10-42

experimental, 10-66

precordial leads, 10-67

standard leads, 10-72

unipolar extremity leads, 10-72

myocardial ischemia, 10-64

myocarditis, 8-76 to 8-78

pararrhythmia, AV dissociation, 11-100 to 11-104

parasystole, 11-104 to 11-106

partial AV block, 11-49

pericardial effusion, 8-37

pericarditis, 8-36 to 8-38

adhesive and constrictive, 8-49

pneumonia, primary atypical, 8-87

polymyelitis with myocarditis, 8-88

precordial pain, 10-65, 10-66

rheumatic fever, aortic insufficiency, 7-73, 7-74

aortic stenosis, 7-73

mitral stenosis, 7-69 to 7-72

tricuspid insufficiency, 7-74

tricuspid stenosis, 7-74

Rickettsial disease, 8-85

SA block, 11-47

sinus arrhythmia, 11-5

sinus bradycardia, 11-5

supraventricular tachycardia, 11-11 to 11-13

surgery of coronary heart disease, 10-103

syphilis, 9-23, 9-24

aortic insufficiency, 9-15

ventricular flutter, 11-35

ventricular tachycardia, 11-18 to 11-23

## Electrokymogram, bundle branch block, left, 11-69

coronary heart disease, 10-86

infarct, anterolateral, 10-86, 10-87

posterolateral, 10-87

mitral insufficiency, 7-102, 7-103

mitral stenosis, 7-102, 7-103

pericarditis, 8-57

rheumatic fever, acute, 7-101

syphilis, aortic aneurysm, 9-28

## Electrokymography, atrial fibrillation, 11-53

atrial flutter, 11-52

AV block, 11-54

bundle branch block, 11-88, 11-89

congenital heart disease, 6-98 to 6-105

coronary heart disease, 10-85 to 10-90

correlation with electrocardiographic findings, 10-86 to 10-90

local paralysis, 10-88

ventricular aneurysm, 10-89

extrapericardial disease, 8-58

intraventricular block, 11-70

## Electrokymography, pericarditis, 8-56 to 8-58

premature beats, 11-54

rheumatic fever, 7-101

rheumatic heart disease, aortic insufficiency, 7-103

aortic stenosis, 7-103

mitral insufficiency, 7-101, 7-102

mitral stenosis, 7-102, 7-103

tricuspid insufficiency, 7-103

syphilis, aortic aneurysm, 9-29

Emboli, coronary, in echinococcus disease, 8-94

pulmonary (see Pulmonary embolism)

Embolization, cerebral, 7-171

Embryologic development of the heart, 6-5 to 6-10

Emesis, coronary artery disease, 10-35

Kussmaul's phenomenon in pericarditis, 8-55

Kymography, teleroentgen, coronary heart disease, 10-82 to 10-84

Lactic dehydrogenase, coronary heart disease, 10-58

Landry-Guillain-Barre syndrome associated with myocarditis, 8-70

Lapex in surgery of mitral stenosis, 7-128

Laryngotracheobronchitis associated with myocarditis, 8-66

Leaflet, congenital cleft, 7-131

shunting, baffle, or "water-shed" function of, 7-118

Left atrial pressure pulses, atrial septal defect, 6-116

normal, 6-114

Left atrium, aneurysmal, 7-135

aortic stenosis, electrokymographic findings, 8-105

dilatation of, 7-22

enlargement, 6-44

esophagus, 6-149

hypertrophy, 7-22

patent ductus arteriosus, electrokymographic findings, 6-103

Left auricular appendage, 6-144

Left heart, atrial septal defect, electrokymographic findings, 6-101

Left heart catheterization, mitral insufficiency, 7-135, 7-138

rheumatic heart disease, 7-110 to 7-116

abnormal pressure measurements and their interpretation, 7-111 to 7-114

aortic insufficiency, 7-112, 7-113

evidence of dynamically significant valvular insufficiency, 7-110, 7-111

evidence of dynamically significant valvular stenosis, 7-110

mitral insufficiency, 7-112

mitral regurgitation, 7-113, 7-114

patterns of pressure, 7-114 to 7-116

Left ventricle, aneurysm of, electrocardiogram, 10-77

aortic stenosis, electrokymographic findings, 8-105

congenital diverticulum of, 6-35

dilatation of, 7-23

enlargement, shunt distal to AV valves, 6-151

hypertrophy of, 7-23

walls, 6-135

increased pressure work of, 6-60

increased volume-flow work of, 6-67

with left auricular appendage, 6-144

overload of, 6-46

roentgenology of, 8-144, 8-145

Left ventricular pressure pulses, normal, 6-114

Lesions, acute, types of, 5-4

chronic, types of, 5-4

degenerative, classification of types, 5-4, 5-5

left side of heart, elevated pulmonary venous pressure, 6-77 to 6-79

pulmonary venous pressure not elevated at birth, 6-74 to 6-77

myocardial, embolic, following bacterial endocarditis, 8-10

types of, 5-4

not associated with a communication, classified, 6-37

pericardial, types of, 5-4

right side of heart, 6-79, 6-80

traumatic, types of, 5-4, 5-5

valvular, with no shunt, 6-93 to 6-97

with right-to-left shunt, 6-93 to 6-97

vascular, with no shunt, 6-93 to 6-97

with right-to-left shunt, 6-93 to 6-97

Leucocytosis, rheumatic fever, 7-34, 7-35

rheumatic pericarditis, 7-32

Levocardia, isolated, 6-32

mixed, 6-32

Levophed, myocardial infarction, 10-55

Libman-Sacks disease associated with myocarditis, 8-70

Ligament of Cross, surgical treatment of patent ductus arteriosus, 6-182

Lipochondrodystrophy, 6-33

Lipoprotein, coronary artery, 10-16

defect joining the two circulations, if the shunt is sufficiently large to utilize the total available vascular bed (Dexter et al., 1950).

**The Volume of Blood Present within the Lungs.** The total vascular bed may be reduced functionally but not anatomically by an increase in pulmonary blood volume, such as the shift of blood from the systemic to the pulmonary circulation following an acute cerebral accident (Sarnoff et al., 1952, 1953).

**Obstruction to the Passage of Blood from the Lungs.** When pulmonary venous obstruction is present, an increase in pulmonary artery pressure is necessary to maintain flow through the lungs (Yu et al.).

**Alterations in Vasomotor Tone.** Finally, it is probable that alterations in pulmonary arterial vasomotor tone (Wood, 1952), and perhaps in pulmonary venous tone as well, may bring about a rise in pulmonary artery pressure and lead eventually to pulmonary arterial hypertrophy and intimal thickening.

In contrast to the normal adult lung, the fetal lung<sup>2</sup> is a high-pressure, high-resistance vascular system. Space occupied by the lungs is reduced, for the diaphragm is high and the chest cage is concave. The pulmonary vessels are surrounded by a liquid, not a gas medium, since the alveoli are filled with amniotic fluid. The presence of fluid rather than air in the alveoli means that the pressure exerted externally on the pulmonary vessels is increased, and consequently a greater intra-arterial pressure is necessary to maintain blood flow. In contrast to the normal adult lung, the number of functioning capillaries and the total available vascular bed are small. The small pulmonary arteries and arterioles of the fetal lung resemble systemic vessels. The media of the small muscular arteries is thick, and the lumen size is small. That the resistance to blood flow through the lung of a fetus is high is attested to by the fact that 50 per cent or more of the right ventricular output bypasses the lungs through the ductus arteriosus into the descending aorta (Reynolds). In fact, the major portion of blood reaching the umbilical cord is contributed by the right ventricle through the ductus arteriosus. Since alterations in pulmonary resistance directly affect the amount of blood passing through the ductus to the umbilical cord, it is

clear that the pulmonary vascular bed plays a vital role in the total circulation during fetal life.

The most important change occurring at the time of birth<sup>3</sup> is a shift in dependence for oxygen from the placenta to the lungs. The first breath expands the lungs with air, which forces amniotic fluid from the bronchi out toward the periphery of the lung, where it is absorbed into the blood stream. The replacement of fluid in the alveoli by air reduces the extravascular pressure exerted upon the pulmonary vessels. Intravascular pressure becomes sufficient to force open new vascular channels. Hence, there is a decrease in pulmonary vascular resistance, which is brought about by the increase in the total capillary bed and the decrease in extravascular pressure and is enhanced by the increase in chest and lung size and the development of intermittent negative intrathoracic pressure. Pulmonary artery pressure falls, the right-to-left shunt through the ductus is obliterated, pulmonary blood flow is increased, and the additional blood returned to the left atrium increases pressure in this chamber and closes the valve of the foramen ovale. In early neonatal life, functional closure of the patent ductus arteriosus and patent foramen ovale is followed by anatomic closure (Patten, 1930).

At birth, pulmonary blood flow, previously only a fraction of the cardiac output, increases two- to tenfold. The available vascular bed, on the other hand, increases many times more. Thus, a change occurs in the ratio of pulmonary flow to available vascular bed. A sufficiently large low-resistance bed is available so that normal increases in pulmonary blood flow do not cause a rise in pulmonary artery pressure. A high pulmonary vasomotor tone is no longer essential to the regulation of pulmonary and placental blood flow. Vasomotor tone, therefore, decreases, and disuse atrophy of the small muscular pulmonary arteries results (Darmann; Ferencz). Thick-walled fetal vessels with a small lumen become thin-walled and obtain a wide lumen. The shift in the structure of the vessels can be demonstrated in the early months of life by a study of the lumen-wall ratios obtained by dividing the lumen diameter by the thickness of the media and intima, respectively.

<sup>2</sup> The fetal circulation is discussed in Part I, Chap. 2 Editor.

<sup>3</sup> See Part I, Chap. 2 Editor.

TABLE G-1. PHYSIOLOGIC INTERPRETATION OF ANATOMIC CLASSIFICATION

Group I Signs and symptoms dependent upon volume of pulmonary blood flow Flow affected by position and size of defect, severity of resistance to right ventricular output, severity of pulmonary venous obstruction

\* Resistance due to either pulmonary stenosis or pulmonary vascular disease

fect the course of the disease. An adequate understanding of pulmonary vascular anatomy and function is, therefore, essential to the correct evaluation of patients with heart disease.

The vascular bed of the normal adult lung is a low-pressure low-resistance system with the capacity to handle right ventricular outputs of three times the normal resting value without significant elevation in pressure.<sup>1</sup> Pulmonary arteries of all sizes are thin-walled and have a large lumen. Unlike systemic arterioles, which possess a muscular media capable of greatly increasing resistance to blood flow, the pulmonary arterioles contain only a few muscle fibers and can offer little resistance to the flow of blood. Pulmonary blood pressure is normally low; however, the pressure may rise under certain abnormal conditions, and if the rise is acute and severe, the thin-walled vessels are stretched beyond their tolerance, rupture of the intima occurs, and arteritis of varying severity follows. The end result is a markedly thickened vessel with a small lumen, extensive intimal proliferation, medial hypertrophy, and fibrosis. If, on the other hand, the rise in pulmonary pressure is chronic and less severe, there re-

sults a gradual hypertrophy of the media of the small pulmonary arteries so that the capacity of the pulmonary arterial bed to withstand and alter pressure is increased.

There are five factors which control vascular resistance and pulmonary pressure.

**The Capacity of the Pulmonary Vascular Bed.** Cournaud and others have demonstrated a change in pressure-flow relationships following reduction of functioning lung mass. After a pneumonectomy, the volume of blood passing through the remaining lung is approximately doubled. Pulmonary arterial pressure is normal at rest, but with exercise, the available pulmonary vascular bed is not sufficiently large to handle the increased cardiac output without a rise in pressure. Frequent elevations of pressure lead to arterial hypertrophy and eventual intimal sclerosis which, in turn, cause an increase in resistance to blood flow. A similar picture develops when sufficient pulmonary tissue is destroyed by such diseases as tuberculosis, emphysema, pulmonary fibrosis, and in childhood, repeated attacks of pneumonitis and asthmatic bronchitis.

**The Volume of Pulmonary Blood Flow.** Elevation of pulmonary artery pressure may result from a left-to-right shunt occurring through a

- Pulmonary valve, bicuspid, 6-35
- deformities of, rheumatic fever, 7-24
- evolution of, 6-8
- involvement, in rheumatic fever, roentgenology of, 7-83
- irregularly formed, 6-35
- murmur arising from, 6-42
- Pulmonary vascular bed, arteriovenous fistula, 6-144
- capacity of, 6-38
- lular dance, 6-143
- lung of normal adult, 6-38
- \* peripheral pulmonary arteries and arterioles, 6-143
- prominent lymphatic channels, 6-144
- roentgenology of, 6-143, 6-144
- Pulmonary vascular disease, cor trauriculare, 6-78
- decreased cardiac activity, 6-45
- marked, with large patent ductus arteriosus, 6-52
- with large ventricular septal defect, 6-53, 6-54
- minimal or absent with small patent ductus arteriosus, 6-51
- minimal or moderate, with large patent ductus arteriosus, 6-51, 6-52
- with large ventricular septal defect, 6-53
- with moderate-sized ventricular defect, 6-54
- with single ventricle, pulmonary stenosis, 6-58, 6-59
- minimal with septum secundum defect, 6-65, 6-66
- and anomaly of pulmonary venous return, 6-66
- minimal with small aortic septal defect, 6-52, 6-53
- minimal with small ventricular defect, 6-54
- moderate to severe, with transposition of great vessels, ventricular septal defect and overriding pulmonary artery, 6-61, 6-62
- moderate with moderate aortic septal defect, 6-52
- moderate with true truncus arteriosus, 6-53
- Pulmonary vascular disease, severe, with patent foramen ovale, 6-68, 6-69
- with transposition of great vessels and ventricular septal defect, 6-61
- Pulmonary vein, anomalous drainage of, 6-144
- effect on right atrium, 6-150, 6-151
- total, into coronary sinus, 6-73
- into portal system, 6-73, 6-74
- anomalous inversions of, cardiac catheterization, 6-129, 6-130
- partial, angiocardiology, 6-167
- drainage defects, 6-72 to 6-74
- classified, 6-37
- entry into systemic circuit, pathogenesis, 6-14
- evolution of, 6-8, 6-9
- right, anomalous drainage of, angiocardiology of, 6-165
- total insertion of, into junction of superior vena cava and right atrium, 6-167, 6-168
- transposition of, phonocardiogram of patient with, 6-97
- Pulmonary venous obstruction, 6-144
- congenital, cor pulmonale, 6-78
- murmurs associated with, 6-78
- therapy, 6-78, 6-79
- venous return, obstruction of, with defects between ventricles or great vessels, 6-63
- partial anomaly of, with septum secundum defect and pulmonary vascular disease, 6-69
- total anomalous, to left innominate vein, 6-73
- to right atrium, 6-73
- to superior vena cava, 6-73
- Pulse, peripheral, congenital heart disease, 6-41
- pressure (see Pressure pulses)
- pulmonary, EKG tracings of patent ductus arteriosus, 6-103
- tracings, in pericarditis, 8-55
- Pulsus alternans, myocarditis, 8-76
- supraventricular tachycardia, 11-9
- Pump-oxygenator, 6-185 to 6-191
- clinical accomplishments with, 6-191
- factors in use of, for open intracardiac surgery, 6-189 to 6-191
- requirements of, to permit open intracardiac surgery, 6-186
- Pyemia, myocarditis, 8-85
- Quinidine, bundle branch blocks, 11-86, 11-87
- cardiac resuscitation, 11-110
- cause of myocarditis, 8-72
- extrasystoles, 11-31, 11-33

 recurrent valvulitis, 7-20  
 relationship to hemolytic streptococci of Lancefield group A, 7-29  
 relationship to rheumatoid arthritis, 7-26, 7-27  
 rest, importance of, 7-40, 7-41  
 rheumatoid arthritis, 7-37  
 roentgenology, 7-75 to 7-83  
 sedimentation rate, 7-34  
   erythrocyte, 7-39  
 serum mucoprotein, 7-41  
 serum sickness reactions, 7-38  
 sickle cell disease, 7-38  
 sinus bradycardia, 7-68  
 sinus tachycardia, 7-68  
 skin rashes, 7-39  
 specific response, 7-13, 7-14  
 steroid therapy, side effects of, 7-43  
 streptococcal infection, 7-36  
   therapy for, 7-31  
   undiagnosed and untreated, 7-31  
 streptococci, 7-3 to 7-11  
 subcutaneous nodules, 7-27, 7-34  
 tachycardia, supraventricular, 7-68  
 tics, 7-39  
 tricuspid insufficiency, electrocardiography, 7-74  
   hypertrophy and dilatation of both right chambers, 7-24  
   roentgenology of, 7-82, 7-83  
 tricuspid stenosis, electrocardiography, 7-74  
   enlargement of right atrium, 7-24  
   roentgenology of, 7-83  
 tricuspid valvular calcification, 7-83  
 valves vascularized, 8-6  
 valvular deformities, 7-20 to 7-24  
 ventricular escapes, 7-68  
 ventricular extrasystoles, 7-68

- Patent foramen ovale, with severe pulmonary valvular stenosis, 6-67, 6-68  
 with severe pulmonary vascular disease, 6-68, 6-69  
 small, with aortic and mitral atresia and patent ductus arteriosus, 6-63, 6-64  
 with congenital mitral stenosis, 6-71, 6-72  
 with transposition of great vessels and patent ductus arteriosus, 6-61
- Patent foramen primum, pathogenesis of, 6-12
- Pathology, arteriosclerosis, 10-12  
 coronary heart disease, 10-8 to 10-28  
 myocarditis, 8-63 to 8-73  
 rheumatic fever, 7-12 to 7-28  
 rheumatic heart disease, 7-12 to 7-28
- Paverl Phosphate, coronary heart disease, 10-48
- Pectus excavatum, 6-33  
 bacterial endocarditis, 8-13  
 long-acting preparations, 8-14  
 myocardial infarction, 10-54  
 myocarditis, 8-83
- Penicillin, pericarditis, 8-40  
 procaine, rheumatic fever, 7-40  
 rheumatic fever, recurrences of, 7-44  
 streptococcal infections, 7-31  
 surgery of mitral stenosis, 7-128  
 syphilis, 9-25
- Pentology of Fallot, angiocardiology, 6-159, 6-160  
 with atrial septal defect, 6-17  
 electrokymographic findings, 6-100
- Perceptual measures, postoperative testing of, 7-169  
 preoperative testing of, 7-168
- Perfusion apparatus used in open intracardiac surgery, 6-190
- Periarteritis nodosa, coronary artery, 10-14  
 with pericarditis, 8-34
- Periarthritis of left shoulder in coronary heart disease, 10-46
- Pericardial cavity, evolution of, 6-5
- Pericardial effusion, circulation time, 8-52  
 echinococcus disease, 8-95  
 electrocardiography, 8-37  
 loculated, roentgenology of, 8-36
- Pericardial lesions, types of, 5-4
- Pericardial tap in pericarditis, 8-41
- Pericardiotomy in pericarditis, 8-42
- Pericarditis, ACTH, use of, 8-41  
 acute, 8-21 to 8-24  
 benign, 8-32, 8-33  
 with myocarditis, 8-80  
 idiopathic, 8-32, 8-33  
 incidence, 8-27  
 nonspecific, Aureomycin in treatment of, 8-33  
 rheumatic carditis, 8-22  
 adhesions, 8-34  
 adhesiva interna, 8-42
- Pericarditis, adhesive, anemia, 8-45  
 angiocardiology, 8-49, 8-50  
 artificial pneumomediastinum, 8-49  
 auscultation, 8-45

 sequelae and complications, 8-47  
 silent type, 8-46  
 slowly progressive type, 8-46  
 stationary type, 8-46  
 superior caval syndrome, 8-47  
 symptoms and signs, 8-42 to 8-45  
 Wenckebach's phenomenon, illustrated, 8-44  
 angiocardiology, 8-38  
 bacterial, incidence, 8-27  
 ballistocardiography, 8-38  
 Bicillin, use of, 8-41  
 Bornholm disease, 8-34  
 caffeine, 8-41  
 caseous necrosis, 8-23  
 causes, 8-27, 8-28  
 cholesterol, clinical aspects of, 8-32  
 classification of types, 5-4  
 clinical aspects of, 8-27 to 8-51  
 codeine, use of, 8-42  
 complications and sequelae, 8-34  
 constrictive (*see* Constrictive pericarditis)  
 coramine, use of, 8-41

- Quinidine, surgery of mitral stenosis, 7-128  
ventricular tachycardia, 11-23, 11-24
- Quinine, extrasystoles, 11-31
- Race, effect of, on death rates, 5-9, 5-10  
on heart disease in India, 5-23  
on rheumatic fever, 7-30
- Refrigeration, 6-185 to 6-192  
clinical accomplishments with, 6-193, 6-194
- Regurgitation, aortic (*see* Aortic regurgitation)  
mitral (*see* Mitral regurgitation)  
stenosis, 7-119  
valvular, hemodynamics of, 7-63 to 7-67  
with valvular stenosis, blood flow across valve, 7-59  
ventriculo-atrial, recording of, with simultaneous recording of forward cardiac output, 7-64
- Resuscitation, cardiac (*see* Cardiac resuscitation)
- Rete chiari, malformations of, 6-34
- Retrograde aortography, surgical treatment of aortopulmonary septal defect, 6-183
- Retrograde block, pararrhythmia, 11-99
- Retrograde conduction, extrasystoles, 11-31
- Revascularization, bilateral ligation of internal mammary arteries, 10-92  
clinical improvement of patient, 10-93  
coronary artery occlusion after, 10-103, 10-104  
extracardiac collaterals, 10-93  
intracardiac collateral blood flow, 10-93  
methods of, 10-91, 10-92  
myocardial contraction, 10-93  
partial occlusion of coronary sinus, 10-92  
results, 10-93, 10-94  
sources of collateral supply, 10-91, 10-92  
tests of, 10-93
- Rhabdomyomas, 6-34
- Rheumatic carditis, active, contraindication to mitral stenosis surgery, 7-124  
acute, 7-17  
with pericarditis, 8-22  
phonocardiogram of, 7-84  
SGO-T, 10-61
- Rheumatic diseases, prevalence of, in India, 5-23
- Rheumatic fever, abdominal pain, 7-37  
acute, electrokymogram of, 7-101  
phonocardiogram of, 7-85  
rheumatic episode, 7-30  
adrenocorticotrophic hormone, 7-42  
ambulation, graduated, 7-41

with a right-to-left shunt. Early onset of fatigue and growth failure are common in both.

*Do symptoms suggest left heart failure?* Orthopnea strongly suggests left heart failure. However, it is not a common finding in early childhood. In infancy and early childhood, pneumonia is frequently the presenting complaint. Left heart failure should always be suspected when a child with pneumonia does not respond to antibiotic therapy.

In noncyanotic patients, hemoptysis usually indicates left heart failure or pulmonary venous obstruction with increased intracapillary pressure. In cyanotic patients, hemoptysis usually occurs from the rupture of a collateral or bronchial vessel and does not indicate left heart failure.

*Do the symptoms suggest right heart failure?* Edema of the extremities is readily discovered in older children. In infants, however, pitting edema is rare, hepatomegaly being the most frequent finding. A history of sudden weight gain is suggestive of the accumulation of edema fluid. Occasionally the history of a decreased urinary output may be obtained.

## PHYSICAL EXAMINATION

*Is the patient well developed and well nourished? Are cyanosis and clubbing present? Is the distribution uniform or unequal?* Failure of development is more common when a cardiac malformation is severe. However, as a differential diagnostic point, failure of development is of no value. The *gracile habitus*, associated in the early literature with an atrial defect, is equally common with all defects (Abbott, 1927, Brown).

The cyanosis of congenital heart disease is usually general, involving primarily the lips and nail beds. If it is confined to the lower extremities and left hand, this finding is pathognomonic of a large patent ductus with reversal of blood flow.

*What is the character of the peripheral pulses?* Carotid, radial, and femoral pulses should be evaluated both for their presence and for their comparative quality. The diagnosis of coarctation of the aorta (particularly in infancy) may rest upon the difference in quality of radial and femoral pulses. A dampened femoral pulse, but active radial pulse, suggests coarctation of the aorta. A bounding

pulse suggests aortic insufficiency or a communication between the aorta and pulmonary artery. A weak pulse, which is difficult to feel, is often present with congestive heart failure. However, it may indicate a decreased systemic flow and the presence of a large left-to-right shunt or obstruction in the outflow tract of the left ventricle.

Particularly in infancy, the feel of the pulse is a more reliable measure of blood pressure than the auscultatory method. A reliable blood pressure reading is difficult to obtain since the size of the cuff used, the thickness of the arm and thigh, and the activity of the infant all cause marked variations.

*Is edema present?* Pitting edema is easily discovered. In early infancy, however, edema does not pit and may be missed. If the skin is thick, pasty, and varies in quality from the extremities to the trunk, it is good evidence that edema is present. The skin of babies with severe forms of congenital heart disease not leading to cardiac decompensation is characteristically loose, easily picked up, and lacking in tone.

*Specific Cardiac Examination. Is there a bulge of the left chest?* Because of the position of the right ventricle close to the chest wall, a bulge of the left chest indicates enlargement of the right ventricle. Such a bulge is not seen with left ventricular enlargement alone.

*Is precordial activity increased or decreased?* Increased activity of the precordium, close to the sternum, suggests a large right ventricle and a high pulmonary artery flow. A comparison of the activity close to the sternum and at the apex should be made, for when the left ventricle does not have an increased work load and the right does, apical pulsations are less than those close to the sternum. Decreased precordial activity suggests stenosis or pulmonary vascular disease. On the other hand, a swing of the chest from left to right with each beat of the heart develops from tricuspid or mitral insufficiency.

*What is the position of the apex?* In infants and children the apex normally can be felt in the 4th left interspace. When it is felt in the 5th left interspace, the probability of left ventricular enlargement must be entertained. If the apex is felt lateral to the midclavicular

The factors controlling pulmonary blood pressure have been previously mentioned. If any one of them is sufficiently altered at birth, the fetal pulmonary vascular pattern will persist (thick-walled pulmonary vessels with a small lumen), and pulmonary hypertension will continue. If an alteration in any factor occurs after disuse atrophy of the small pulmonary vessels has taken place, medial hypertrophy must be reacquired and the likelihood of significant vascular injury is greatly increased. As a consequence, *the picture of pulmonary hypertension in malformations active at birth is one of marked medial hypertrophy with little intimal change, whereas medial hypertrophy is less extensive and intimal proliferation and scarring are more common when pulmonary hypertension occurs at a later date*

The importance of pulmonary hypertension in congenital heart disease is obvious. Of equal importance to the presence of pulmonary hypertension, however, is the method by which that hypertension was brought about, the time it occurred, and the specific response of the pulmonary vascular bed to it (Dammann, 1958). It is only with a full understanding of these factors that proper selection of patients for cardiac surgery can be made. For example, patients with an atrial septal defect who develop pulmonary vascular disease, right heart failure, and a reversal of shunt are poor candidates for closure of the defect because the pulmonary vascular disease is in good part irreversible, consisting primarily of marked intimal thickening. On the other hand, the patient with a large patent ductus and pulmonary hypertension, where the shunt is predominantly left to right, can be greatly assisted by closure of the ductus, for medial hypertrophy of the small pulmonary vessels is the predominant morphologic change and such hypertrophy is reversible once the stimulating mechanism is removed.

The accurate diagnosis of congenital heart disease depends upon the correct interpretation of all available data. Adequate data can be obtained and properly assessed if a routine plan of investigation is adhered to. The basic approach is to isolate that portion of the circulatory system which is under stress, to determine when stress first appeared, and to assess its magnitude. The answers to these questions should be obtained.

## HISTORY

*At what age did symptoms appear? Have they increased, remained stationary, or decreased in severity?* We have found it very useful to obtain a detailed developmental history. It is common for patients with a ventricular septal defect, for example, to appear normal at birth, show poor weight gain, rapid respiration, and susceptibility to pulmonary infections for the first year or two and then to improve. The improvement may be sufficient to make both doctor and parent assume that the defect is no longer important. This period of well being—the “golden period”—is temporary, however, and leads to a gradual downhill course characterized by increasing cyanosis and decreasing exercise tolerance. In contrast, patients with an atrial septal defect usually do well in the first years of life, and the appearance and progression of symptoms is relatively late and slow.

*When was the murmur first heard?* If a systolic murmur was heard in the newborn period, the diagnosis of valvular or subvalvular stenosis or a small ventricular septal defect is suggested. A murmur is rarely heard in the newborn infant due to a patent ductus arteriosus, a transposition of the great vessels, a large ventricular defect, or an atrial defect.

*Do the symptoms suggest a right-to-left shunt?* Cyanosis suggests a right-to-left shunt although the cyanosis of venous stasis secondary to right heart failure and deficient oxygenation from other causes must be ruled out. The cyanosis of congenital heart disease involves primarily the lips and nail beds. Unless parents are questioned carefully, the examiner may be misled, for many normal children have transient cyanosis around the mouth, but not of the lips alone. The history of transient cyanosis in the newborn period is not uncommon in patients with septal defects or isolated valvular pulmonary stenosis.

*Do symptoms suggest a left-to-right shunt?* Repeated pulmonary infections are far more commonly seen when a left-to-right shunt is present than when the shunt is right to left. Exertional dyspnea is usually less severe than

\* The history and physical examination in children have been discussed in Part 3, Chap. 10. Editor.

- Venous return, pulmonary (*see* Pulmonary venous return)
- Ventricles, defects between, classified, 6-57  
 with obstruction of pulmonary venous return, 6-63
- diverticulum of, etiology, 10-105
- large defects between, 6-45 to 6-51  
 with minimal right ventricular outflow obstruction, 6-48  
 with moderate right ventricular outflow obstruction, 6-49  
 with severe right ventricular outflow obstruction, 6-49  
 with transposition of great vessels and two vessels originating from right ventricle, 6-62
- left (*see* Left ventricle)
- medium-sized defect with moderate right ventricular outflow obstruction, 6-50  
 with marked right ventricular outflow obstruction, 6-50  
 with minimal right ventricular outflow obstruction, 6-49, 6-50  
 with minimal to moderate pulmonary vascular disease, 6-54
- right (*see* Right ventricle)
- single, cardiac catheterization of, 6-124  
 with diminutive outlet chamber, 6-22  
 with pulmonary stenosis, 6-59  
 with pulmonary stenosis and pulmonary vascular disease, 6-58, 6-59
- small defect, with marked right ventricular outflow obstruction, 6-50, 6-51  
 with minimal pulmonary vascular disease, 6-54  
 with minimal right ventricular outflow obstruction, 6-50  
 with moderate right ventricular outflow obstruction, 6-50
- Ventricular activation, 11-70 to 11-74
- Ventricular aneurysm, coronary heart disease, 10-44, 10-89  
 following coronary arterial occlusion, 10-16  
 roentgenology, 10-106  
 surgery of, 10-105 to 10-109  
 diagnosis, 10-107, 10-108  
 etiology, 10-105, 10-106  
 following coronary arterial occlusion, 10-16  
 pathophysiology, 10-106, 10-107  
 posttraumatic aneurysms, 10-106  
 results, 10-109  
 selection of patient, 10-107, 10-108  
 technique, 10-109
- Ventricular arterIALIZATION by vascular anastomosis, 10-99, 10-100
- Ventricular escapes, rheumatic fever, 7-69
- Ventricular extrasystoles, rheumatic fever, 7-69  
 rheumatic heart disease, 7-45
- Ventricular fibrillation, 11-39, 11-40  
 cardiac resuscitation, 11-107, 11-108, 11-110, 11-112

- Surgery, open intracardiac, acquisition of dry, quiet field, 6-183 to 6-191  
adequate extracorporeal gas exchange, 6-186  
clinical accomplishments with pump-oxygenator, 6-191  
control of clotting, 6-187  
Dale-Schuster pattern, 6-186  
DeBakey pattern, 6-186  
efficient nontraumatic pumps, 6-186, 6-187  
electrically induced ventricular fibrillation, 6-189, 6-190  
finger pumps, 6-186, 6-187  
gravity siphonage, 6-187  
heparin-protamine titration, 6-187  
heparinization, 6-187  
hypothermia, uses of, 6-191 to 6-194  
minimization of metabolic changes, 6-189  
need for both pump and oxygenator, 6-186  
perfusion apparatus for cardiac failure, 6-190  
prevention of embolization of gas or fibrin, 6-188  
prevention of injury to formed elements of blood, 6-187, 6-188  
protamine sulfate, 6-187  
pump-oxygenator in association with hypothermia, 6-190, 6-191
- patent ductus arteriosus, 6-180 to 6-183  
indications for, 6-181, 6-182  
ligament of Gross, 6-182  
posterolateral incision, 6-182  
Potts' technique, 6-182  
results, 6-182, 6-183  
techniques, 6-181, 6-182  
typical, 6-182
- of patients with delusions and hallucinations, 7-162
- psychologic functions, disturbances in, 7-162 to 7-171
- psychological testing of patients before, 7-163 to 7-165
- pulmonary stenosis, cardiopulmonary bypass, 6-172  
indications for, 6-169, 6-170  
isolated infundibular, 6-172  
with normal aortic root, 6-169 to 6-172  
Swan's transpulmonary arterial method, 6-171  
rheumatic heart disease, postoperative organic test battery, 7-163  
postoperative testing of perceptual measures, 7-169  
preoperative organic test battery, 7-168  
preoperative testing of perceptual measures, 7-168  
psychologic impairment after surgery, 7-168  
supraventricular tachycardia, 11-16  
syphilis, 9-23, 9-26
- transposition of great arteries, 6-177 to 6-179  
operative procedure, 6-178  
results, 6-178, 6-179
- Surgery, tricuspid stenosis, 7-158 to 7-161  
clinical classification, 7-158  
cyanosis, 7-159  
diagnosis, 7-158  
diminished pulmonary arterial dimensions seen radiologically, 7-159  
hemodynamic abnormalities, 7-159  
history and cardiac findings, 7-159  
localized diastolic murmur at lower end of sternum, 7-159  
right atrial enlargement, 7-159  
right heart catheterization, 7-158  
treatment, 7-159  
venous pulsation, 7-159
- ventricular aneurysms, 10-105 to 10-109  
diagnosis, 10-107, 10-108  
etiology, 10-105, 10-106  
following coronary arterial occlusion, 10-106  
pathophysiology, 10-106, 10-107  
posttraumatic aneurysms, 10-106  
results, 10-109  
selection of patient, 10-107, 10-108  
surgical technique, 10-109
- ventricular septal defects, 6-173 to 6-176  
method, 6-174, 6-175  
results, 6-175, 6-176
- Swan's transpulmonary arterial method, 6-171
- Sympathectomy, bilateral lumbar, syphilis, 9-26
- Syncope, rheumatic heart disease, 7-51, 7-52
- Syphilis, aorta, fusiform aneurysm, 9-3  
gumma, 9-4  
perivascular infiltration, 9-4, 9-5  
saccular aneurysm, 9-3
- aortic aneurysm, clinical course, 9-18  
etiology, 9-17  
pathology, 9-17, 9-18  
pulmonary artery compression, 9-19, 9-20  
signs, 9-19, 9-20  
symptoms, 9-18, 9-19
- aortic dilatation, roentgenology, 9-12  
signs, 9-11, 9-12  
symptoms, 9-11
- aortic insufficiency, bacterial endocarditis, 9-16, 9-17  
differential diagnosis, 9-15, 9-16  
signs, 9-14, 9-15  
symptoms, 9-14
- aortic valve, 9-7
- aortitis, 9-4 to 9-8, 9-10  
coronary heart disease, 10-31  
arteriosclerosis, 9-6  
associated with myocarditis, 8-66  
AV block, 11-43  
bacterial endocarditis, 8-5  
prognosis, 9-17  
cardiography, aortic aneurysm, 9-27  
cerebrospinal fluid, examination of, 9-10  
clinical aspects of, 9-9 to 9-26  
coronary arteries, 9-8

- Ventricular fibrillation, cardiac resuscitation,  
 graphic data, 11-113  
 countershock, 11-112  
 defibrillation, 11-112  
 electrically induced in open intracardiac sur-  
 gery, 6-189, 6-190  
 hypothermia, 6-192  
 mechanism of origin, 11-40  
 myocardial infarction, 10-58  
 paroxysmal tachycardia, 11-8  
 Ventricular flutter, 11-39, 11-40  
 electrocardiography, 11-35  
 mechanism of origin, 11-40  
 myocardial infarction, 10-58  
 paroxysmal tachycardia, 11-8  
 ventricular tachycardia, 11-20  
 Ventricular hypertrophy, bundle branch block,  
 11-82  
 left, 11-66  
 right, 11-68  
 intraventricular block, 11-70  
 left, 7-23  
 aortic insufficiency, 7-23  
 coronary heart disease, 10-42  
 walls, 6-135  
 right, 6-46  
 deformities of pulmonic valve, 7-24  
 walls, 6-135  
 vectorcardiography, 11-82  
 Ventricular region, evolution of, 6-5  
 Ventricular repolarization, bundle branch block,  
 left, 11-79, 11-80  
 Ventricular septal defect, angiocardography,  
 6-155 to 6-157  
 cardiac catheterization of, 6-123, 6-124  
 closures of, and age, death rates, 6-175  
 with congenital mitral stenosis, 6-64  
 with corrected transposition of great vessels,  
 6-55, 6-56  
 electrokymographic findings, 6-101, 6-102  
 in families, 6-3  
 isolated, complexes associated with, 6-26  
 large, cardiac catheterization of, 6-119  
 with marked pulmonary vascular disease,  
 6-53, 6-54  
 with minimal or moderate pulmonary vascu-  
 lar disease, 6-53  
 with transposition of great vessels and pul-  
 monary vascular disease, 6-61  
 with transposition of great vessels, overriding  
 pulmonary artery and pulmonary vascular  
 disease, 6-61, 6-62  
 with mitral atresia and patent foramen ovale,  
 6-64  
 murmurs, 6-90, 6-91  
 phonocardiogram of patient with, 6-91  
 pulmonary arterial engorgement, 6-150  
 roentgenology, 6-140  
 small, cardiac catheterization, 6-118  
 Ventricular septal defect, sounds, 6-90  
 surgical treatment, 6-163 to 6-167  
 method, 6-174, 6-175  
 results, 6-175, 6-176  
 with transposition of great vessels, 6-60, 6-61  
 with transposition of great vessels and pulmo-  
 nary stenosis, 6-62  
 Ventricular septum, defects of, pathogenesis, 6-12  
 evolution of, 6-7  
 intact, with closed foramen ovale and valvular  
 pulmonary stenosis, 6-79  
 with isolated infundibular pulmonary steno-  
 sis and closed foramen ovale, 6-79  
 transposition complexes, 6-13  
 Ventricular standstill, cardiac resuscitation, 11-107,  
 11-110  
 Ventricular tachycardia, arterial tracing, 11-52  
 atrial fibrillation, 11-21  
 attack, 11-58, 11-59  
 bundle branch block, 11-21, 11-22  
 cardiac resuscitation, 11-109  
 clinical aspects, 11-17  
 clinically normal hearts, 11-23  
 differential diagnosis, 11-22  
 digitalis, 11-25  
 effect of sex on, 11-23  
 electrocardiogram, 11-19 to 11-21  
 electrocardiography, 11-18 to 11-23  
 esophageal leads, 11-22  
 heart failure, 11-24  
 jugular tracing, 11-52  
 mechanism, 11-23  
 Mobitz's interference dissociation, 11-22  
 myocardial diseases, 11-23  
 myocardial infarction, 10-78, 11-24  
 myocarditis, 8-78  
 occurrence, 11-23, 11-23  
 pararrhythmia, 11-21  
 pathology, 11-23, 11-24  
 phonocardiogram, 11-59  
 phonocardiography, 11-58, 11-59  
 posttachycardial syndrome, 11-26, 11-59  
 prognosis, 11-24  
 pronestyl, 11-23 to 11-24  
 reflex vagal stimulation, 11-22  
 retrograde conduction, 11-21  
 symptoms and signs, 11-17, 11-18  
 treatment, 11-24, 11-25  
 ventricular complexes, alternating, 11-19  
 polymorphic, 11-19  
 ventricular flutter, 11-20  
 Ventriculo-atrial regurgitation, recording of, with  
 simultaneous recording of forward cardiac  
 output, 7-64  
 Ventriculography, surgery, mitral insufficiency,  
 7-136, 7-137  
 Venturi effects, pulmonary stenosis, 6-125  
 Viral disease, associated with myocarditis, 8-86 to  
 8-88

- Surgery, aortic insufficiency, chronic, 7-153, 7-154  
 flap-type valve, 7-156  
 helical spring-type valve, 7-156  
 plastic ball-valve prosthesis, 7-155  
 selection of patients for, 7-154  
 slowly progressive, 7-154  
 use of hypothermia, 7-156, 7-157
- aortic stenosis, 7-142 to 7-152  
 advanced state but not terminal, 7-155  
 clinical classification of, 7-143 to 7-145  
 clinical correlation of pathophysiologic changes, 7-143  
 clinical results, 7-150, 7-151  
 cusp-type valve, 7-156  
 deaths, late, 7-150  
 operative, 7-150  
 hemodynamic observations, 7-149, 7-150  
 history of aortic valve surgery, 7-145 to 7-149  
 orifice increased, 7-149  
 pathophysiologic changes, 7-142, 7-143  
 transventricular approach to, 7-146 to 7-149
- aortopulmonary septal defect, 6-183, 6-184
- constrictive pericarditis, 8-59 to 8-62  
 atrial fibrillation, 8-60  
 diagnosis, 8-60  
 indications for operation, 8-60  
 paradoxical pulse, 8-60  
 preoperative preparation, 8-60, 8-61  
 results, 8-62  
 surgical technique, 8-61
- coronary heart disease, 10-95 to 10-104  
 anticoagulant therapy, 10-102  
 arterialization of coronary sinus, 10-99  
 bilateral ligation of internal mammary arteries, 10-97  
 blood pressure, 10-102  
 cardiac vein ligation, 10-97  
 cardiopneumopexy, 10-98  
 cervicothoracic ganglionectomy, 10-96  
 classification of operations, 10-95  
 contraindications for, 10-101, 10-102  
 coronary sinus ligation, 10-97  
 development of collaterals, anastomoses, or both, 10-97  
 diagnosis, 10-102  
 direct attack on diseased coronary arteries, 10-97  
 electrocardiography, 10-103  
 failure to develop fresh infarction, 10-103, 10-104  
 fluid balance, 10-102  
 indications for, 10-100, 10-101  
 interruption of cardiac pain fibers, 10-96  
 myocardial vascularization by extracardiac blood, 10-97, 10-98  
 neurosurgery to block afferent pathways, 10-96, 10-97
- Surgery, coronary heart disease, objectives, 10-94 to 10-100  
 operative care, 10-102  
 pericardial fat pad grafts, 10-98  
 pericoronary neurectomy, 10-96  
 posterior rhizotomy, 10-96  
 postoperative care, 10-102  
 precordial pain, 10-103  
 preoperative investigation, 10-102  
 results, 10-102 to 10-104  
 selection of operative procedure, 10-100  
 selection of patients, 10-100  
 surface grafts, 10-98, 10-99  
 survival, 10-103  
 ventricular arterialization by vascular implants, 10-99, 10-100
- mitral insufficiency, 7-131 to 7-141  
 circumclusion technique, 7-137  
 closed polar plication technique, 7-138  
 electrocardiogram, 7-134  
 elevation of a leaflet, 7-137  
 etiology, 7-131, 7-132  
 introducing living tissue and prostheses, 7-137  
 pathology, 7-131, 7-132  
 physiology, 7-132, 7-133  
 plication or distortion of mitral annulus, 7-137  
 polar cross, closed technique with bypass assistance, 7-140, 7-141  
 closed technique without bypass, 7-135 to 7-140  
 open technique, 7-141  
 roentgenology, 7-135  
 signs, 7-134  
 suturing one leaflet to the other, 7-137  
 ventriculography, 7-136, 7-137
- mitral stenosis, 7-117 to 7-130  
 anesthesia, 7-125, 7-126  
 with associated severe aortic disease, 7-123  
 atrial fibrillation, 7-123  
 calcification of mitral valve, 7-123  
 cardiovascular diseases, 7-124  
 effects of age, 7-123  
 extrinsic baffle, 7-120  
 function of leaflets, 7-118  
 insufficiency better tolerated than stenosis  
 erroneous concept, 7-117  
 morphologic classification of, 7-118 to 7-121  
 operation, 7-126 to 7-129  
 preoperative preparation, 7-125  
 rheumatic carditis, active, 7-124  
 selection of patients, 7-124, 7-125  
 symptoms, 7-133, 7-134  
 total surgical management, 7-125 to 7-129  
 valvuloplasty, completion of, 7-128  
 finger fracture technique, 7-127  
 results, 7-129, 7-130  
 neuropsychiatric complications in, 7-162 to 7-171

- Valvuloplasty, derivation of term, 7-118  
 finger fracture technique, 7-127  
*mitral stenosis, with mitral insufficiency*, 7-123  
 technical considerations in, 7-118 to 7-121
- Valvulotomy, combined valvular and infundibular stenosis, 6-126  
 pulmonary valvular stenosis, 6-126  
*pulmonic stenosis*, 6-127

line in the 4th left interspace, it suggests right ventricular enlargement alone.

**Auscultatory Findings.** Much information can be obtained from a proper evaluation of *murmurs*. The point of maximal intensity, distribution over the precordium, distribution to the axillae and to the great vessels of the neck, timing, duration, and quality of the murmur all are important

**POINT OF MAXIMUM INTENSITY** In general, a *systolic murmur*, maximal at the base of the heart in the 2d and 3d interspace, suggests relative or absolute *obstruction* of the pulmonary or aortic orifices, ventricular defect, or tricuspid insufficiency. A *systolic murmur* maximal at the apex suggests mitral or occasionally tricuspid insufficiency

**DISTRIBUTION.** Certain congenital malformations of the heart are characterized by a distinctive distribution of the murmur. For example, the murmur of isolated valvular pulmonary stenosis is maximal in the 2d left interspace, is very well transmitted up toward the left clavicle, and is frequently associated with a *thrill* over the left clavicle. In older children, the murmur of aortic or subaortic stenosis is heard best to the right of the sternum in the 1st and 2d right interspace and is well transmitted along the great vessels to the neck. In infants, however, it may be heard best low over the sternum to the left of the midline

It is important to evaluate the distribution of the murmur carefully. The stethoscope should be moved from the point of maximal intensity in all directions to determine where the murmur is best transmitted. Not infrequently, a *systolic murmur* may be well transmitted to the left axilla, suggest-

mitted out along the pulmonary artery rather than arising from the mitral valve. The presence of a thrill is helpful, not only in locating a point of maximal intensity of a murmur, but in evaluating distribution.

**DURATION AND QUALITY.** In the presence of aortic and pulmonary stenosis, a *long murmur*, which occupies all of systole, suggests that stenosis is severe. A *short systolic murmur*, on the other hand, indicates that the ventricle empties relatively rapidly and, therefore, that the stenosis is not severe. A *high-pitched murmur* indicates markedly increased velocity of

blood flow through a defect or a point of obstruction. High velocity can occur only if the pressure differential is great. Consequently, a high-pitched systolic murmur would suggest a pulmonary or aortic stenosis with a high ventricular and low distal artery pressure or a small ventricular defect with normal right and left ventricular pressures.

If a *diastolic murmur* is present, it first must be determined if this murmur is a continuation into diastole of a murmur heard in systole or whether it is separate and distinct. The murmur of a patent ductus arteriosus is *continuous*. If the murmur fades out and then starts again with increased intensity in the early part of diastole, it is *to and fro* and not continuous. A *decrecendo diastolic murmur*, either short or long, usually soft and blowing in quality, indicates pulmonary or aortic insufficiency. If arising from the aortic valve, the murmur can be heard along both sides of the sternum over the base of the heart and down toward the xiphoid process. If it arises from the pulmonary valve, it is usually not heard to the right of the sternum near the xiphoid process. A common diastolic murmur is an *early, low-pitched diastolic sound located along the left sternal border*. The etiology of this murmur is obscure, but it is associated with a large and greatly overworked heart. A *mid-diastolic rumble* out toward the apex or between the apex and the sternum suggests a relative mitral or tricuspid stenosis. It is common in lesions causing a high return of blood to the left atrium, such as a patent ductus arteriosus or ventricular septal defect and also in patients with an atrial septal defect who have a large volume of blood passing from a large right atrium into a large right ventricle.

**EXTRACARDIAC MURMURS** In patients with severe pulmonary stenosis, *collateral vessels to the lungs* may cause a *blowing continuous murmur*, heard over both chests anteriorly and posteriorly but not maximally over the 2d left interspace. A *low-pitched continuous bruit* may also be heard in coarctation of the aorta because of collateral circulation in the chest wall. A *mid-systolic murmur*, not particularly loud and poorly localized, heard well over the back and over the base of the heart, is the usual murmur associated with coarctation of the aorta. A *continuous murmur* or *pure sys-*

terior oblique, and if the interventricular groove can be seen in the left anterior oblique position, the groove will lie abnormally far posteriorly. *Enlargement of the left ventricle* tends to make the heart assume a more vertical position, with the long axis of the heart lying at a 45° angle rather than horizontally. The apex of the heart does not clear the diaphragm on deep inspiration, and in the LAO view there is posterior rounding of the ventricle and a reduction of the retrocardiac space. However, if there is marked enlargement of either the right or left ventricle, the opposite ventricle may be displaced in such a way that it appears enlarged. *Right atrial enlargement* is best determined in the LAO and PA views. In the LAO view, a shelf may be seen extending from the pulmonary artery anteriorly toward the chest wall, representing an enlarged right auricular appendage. In the PA projection, cardiac rounding to the right of the spine suggests *enlargement of the right atrium*. *Enlargement of the left atrium* is determined by a study of the barium-filled esophagus and the position of the left main stem bronchus. Elevation of the left main stem bronchus when seen in the LAO view indicates left atrial enlargement. The barium-filled esophagus over a short distance will be displaced to the right in the PA projection when the left atrium is enlarged.

*What is the origin, position, course, and size of the two great vessels arising from the heart?* The answer to this question is frequently difficult since vessel origin may appear displaced because of rotation of the entire heart. Right ventricular enlargement tends to rotate the heart in a clockwise manner when looked on from below. In so doing, the main pulmonary artery segment is accentuated and the ascending aorta becomes less apparent. When the left ventricle is enlarged, rotation in a counterclockwise fashion occurs. This tends to bring the origin of the pulmonary artery anteriorly and thus make the main pulmonary artery shadow as seen in the PA view concave. In a similar manner, the ascending aorta becomes more prominent. Rotation of the heart can be compensated for by careful rotation of the patient under the fluoroscopic screen. Thus, a full main pulmonary artery segment lying anteriorly because of clockwise rotation of the heart will appear convex and large by rotation into the RAO view. If heavy

pulmonary vascular markings are present in the peripheral lung fields, if a large right and left pulmonary artery are visualized, and if in the PA projection the pulmonary artery is concave and does not become concave on rotation into the RAO view, it is probable that the *origin of the pulmonary artery is anatomically displaced*.

A word of caution should be given against excessive reliance on *evaluation of pulmonary vascular markings*. The increased collateral circulation to the lungs in the presence of severe pulmonary stenosis can be mistaken for increased vascularity. Pulsations in the pulmonary vessels do not of necessity indicate increased pulmonary blood flow. Pulsations are dependent upon the thickness of the vessel wall and the amplitude of pulse pressure, as well as the volume of blood flow. The apparent size of the pulmonary vessels and the number of vessels seen on x-ray theoretically should indicate whether flow or pressure to the lung is increased or decreased. However, technical differences in obtaining and developing the x-ray may emphasize or deemphasize the vascular markings, leading to a wrong interpretation. Except when the changes are marked, evaluation of the pulmonary vascular markings is frequently in error.

The course and size of the *aorta* are best determined by a study of the barium-filled esophagus. The presence of a *right aortic arch* is suggested if the aorta is seen pushing the esophagus to the left in the PA projection and posteriorly in the LAO view. The normally positioned aorta deflects the esophagus to the right in the PA projection and posteriorly in the LAO view. In the presence of a *coarctation of the aorta*, careful examination of the patient in the LAO view may reveal the presence of a dilated segment of aorta immediately distal to the coarctation. Dilatation of the ascending aorta suggests *aortic stenosis*. A dilated ascending aorta with a definite incisura at the point where the right atrium overlaps the aorta in the PA projection is good evidence of *valvular aortic stenosis*, whereas a dilated aorta with complete blending of right atrial and aortic shadows without incisura suggests *subaortic stenosis*.

*What is the activity of the heart and great vessels?* In the presence of a large left-to-right ventricular shunt, the activity of both right and

*toic murmur* may be heard over one or both lung fields, arising from single or multiple coarctations of the pulmonary artery branches.

**SECOND HEART SOUND.** A split 2d sound suggests that both aortic and pulmonary valves are functioning, and hence a severe valvular pulmonic or aortic stenosis is not present. A quiet 2d sound to the left of the sternum suggests a decreased pulmonary blood flow. However, it must be remembered that, in the presence of a tetralogy of Fallot, the position and size of the aorta accentuate the aortic 2d sound in the 2d left interspace. In this condition, a loud pure 2d sound in the 2d left interspace does not rule out decreased pulmonary blood flow. An accentuated and split 2d sound suggests increased pulmonary blood flow probably associated with increased pulmonary pressure.

**Examination of Lungs.** Rales, inspiratory and expiratory wheezes, may be present in patients with congestive heart failure as well as with pulmonary infections. In infants, however, rales may not be present even when failure is severe. Decreased breath sounds over the left base posteriorly suggest marked enlargement of the left side of the heart with compression atelectasis of the left lower lobe. This is an infrequent finding when cardiac enlargement is of the right side alone. In evaluating the chest, it is well to listen twice, once for murmurs and secondly for abnormal pulmonary sounds.

**Abdomen.** The size and character of the liver are of primary importance in the examination of the abdomen. In infancy, the liver characteristically can be felt 1 to 3 cm below the right costal margin. Under such circumstances, evaluation of the liver rests upon the consistency of the edge that is palpable rather than size. A sharp firm edge indicates hepatic congestion. An enlarged spleen may be palpated in patients with cyanotic congenital heart disease. As a general rule, the greater the degree of polycythemia, the more likely one is to feel an enlarged spleen.

## X-RAY AND FLUOROSCOPY

To obtain the maximum amount of information, the fluoroscopic examination should be carried out by the examiner who has taken the history and done the physical examination, as well as by the radiologist. It is only in

this way that sufficient attention can be given to differential points. In infancy, the fluoroscopic examination is vastly more informative than the x-ray examination.

An infant's rapid respirations make it difficult to obtain a roentgenogram at the peak of inspiration when the diaphragm is lowest and the mediastinal shadow the narrowest. More important, some degree of rotation of the chest is almost always present. Rotation accentuates the wide mediastinal shadow normally present and obscures the contour of the heart. It should be the policy to obtain x-rays on the small infant in order to have a permanent record for comparison with films taken at an older age, but the findings by x-ray are not accepted as accurate unless they have been confirmed by a fluoroscopic examination.

In general, the fluoroscopic and x-ray examination of the heart should be aimed at answering the following questions:

*Is the heart normal in size or enlarged?*

Evaluation of the heart size in the small infant is difficult because the heart lies transversely because of a high diaphragm, and thus, in the posteroanterior view, its width is increased. As a child grows and the chest lengthens, the diaphragm assumes a lower position. The heart tends to be in a more vertical plane, and the ratio of width of heart to width of chest is more significant. Despite the difficulty of absolute measurement of heart size in a small child, an impression of size can be gained which may be helpful in establishing a diagnosis. The heart of a child with pulmonary stenosis and a ventricular septal defect tends to be small, whereas that of a child with a transposition of the great vessels tends to be increased in size. Thus, when cyanosis is present, an impression of the heart size is helpful in differentiating the malformations. In non-cyanotic patients with defects between the two sides of the heart, the heart size gives some indication of volume of flow through the defect. When pulmonary resistance is high and pulmonary blood flow low, heart size tends to be within normal limits, but when the pulmonary resistance is low and the volume of shunt from left to right through the defect is large, the heart size is increased.

*What specific cardiac chambers have been altered in size and contour?* The enlarged right ventricle tends to enlarge the heart transversely in the PA projection, anteriorly in the right an-

The "systolic" and "diastolic overload" patterns have been of definite help in differential diagnosis.

The degree of *right ventricular hypertrophy*, as determined by the ECG, is of value in differential diagnosis, as well as in determining the magnitude of stress placed on the heart. In the presence of pulmonary stenosis with a large ventricular septal defect (*tetralogy of Fallot*), the right ventricle must develop sufficient contractile strength to force blood out through the stenotic pulmonary orifice or through the ventricular defect into the aorta. Because of the ventricular defect, the maximum required work of the right ventricle is merely enough work to overcome systemic resistance. As a consequence, the degree of hypertrophy is not great. On the other hand, when there is *pulmonic stenosis with an intact ventricular septum*, the right ventricle has no escape valve and must overcome the resistance offered by the stenotic pulmonary valve. When stenosis is severe, marked right ventricular hypertrophy of the systolic overload form is present in the ECG. A right ventricular strain pattern is common in this malformation but extremely rare in patients with the typical tetralogy of Fallot.

*Systolic overload of the left ventricle* is characterized by an S in  $V_1$  plus an R in  $V_5$  and  $V_6$  of more than 35 mm. The interval from Q to the peak of the intrinsic deflection in the left precordial leads is greater than 0.05 sec. The *left ventricular diastolic overload* pattern is characterized by elevation of the S-T segment in leads facing the left ventricle and an upright, peaked T wave. These patterns are less clear-cut than similar patterns for the right ventricle, and hence, their value in differential diagnosis is less reliable.

Some evidence concerning stress placed on the atria can be obtained from the ECG. A tall, peaked P wave in leads II, III, aVF, and over the right chest leads suggests *right atrial enlargement and hypertrophy*. A notched P wave in leads I, II, aVL, a biphasic P wave in  $V_1$ , and a large P wave with a short P-R interval over the chest leads is evidence of *left atrial enlargement and hypertrophy*.

There are serious pitfalls in the interpretation of the ECG. An abnormal position or unusual rotation of the heart alters the electrocardiographic pattern and may suggest an incorrect

diagnosis. Unusual conduction disturbances may be mistaken for hypertrophy patterns. *Failure of one ventricle* may be associated with a decrease in electrical activity and relative preponderance of the other ventricle in the ECG. Such a pattern has been described in patients with extreme valvular pulmonary stenosis where there is a greatly dilated and thin-walled right ventricle associated with electrocardiographic evidence of left ventricular preponderance.

One point of diagnosis should be strongly emphasized: the clinical findings and laboratory results must all fit together and direct attention toward the correct diagnosis. If there are discrepancies, an explanation for the discrepancies must be given, or the diagnosis may well prove wrong.

## CLASSIFICATION OF CONGENITAL HEART DISEASE

The classification of congenital heart disease presented here is divided into two parts. In part one (outline at beginning of chapter), the classification is based upon the type of defect without reference to whether pulmonary stenosis or pulmonary vascular disease complicates the defect and without reference to the direction of the shunt. In part two (Table 6-1), the factors which control the clinical picture presented by specific malformations are correlated and analyzed. Each group of defects will be discussed first as a unit, with emphasis placed on the alterations in hemodynamics produced by the size of the defect and by varying degrees of pulmonary stenosis or pulmonary vascular disease (right ventricular outflow obstruction). The purpose of doing this is not only to save repetition, but to emphasize that, from the physiologic standpoint, a large patent ductus arteriosus is essentially the same as a large ventricular defect, and a ventricular septal defect associated with severe pulmonary stenosis (*tetralogy of Fallot*) is similar to a large ventricular defect with advanced pulmonary vascular disease (Eisenmenger's syndrome). Once having established the similarities within each group, the differential diagnostic points can be brought out in a discussion of each specific malformation.

The estimated frequency of clinical syndromes for each defect is presented in Table 6-2.

left ventricle and pulmonary arteries is increased. If the shunt is at the atrial level, the activity of the heart (in the left oblique) is increased anteriorly, but not posteriorly, suggesting that the right ventricle is handling a greater volume of blood than normal. When a patent ductus is present, both the ascending aorta and pulmonary artery may be quite active. If, however, the defect is intracardiac and the shunt from left to right, the aorta appears quiet and smaller than normal. Tricuspid insufficiency is suggested by increased activity of the right ventricle.

the RAO view.

In contrast to the actively pulsatile pulmonary vessels and heart of a patient with a large left-to-right shunt, pulmonary stenosis, aortic stenosis, and marked pulmonary vascular disease are characterized by a decreased cardiac activity. In patients with an anomalous left coronary artery arising from the pulmonary artery or with endocardial fibroelastosis, the left ventricle, although large, is strikingly quiet. Aortic stenosis is suggested by a delayed and slow pulse wave of the ascending aorta. Aortic insufficiency or a left-to-right shunt between the aorta and pulmonary artery is suggested by rapid filling and emptying of the aorta, with an accentuation of the aortic pulsations.

## ELECTROCARDIOGRAM

A few general principles of electrocardiography will be discussed in this chapter; a more detailed analysis may be found in Chap. 5.

In the newborn baby, the right and left ventricles are of equal thickness and equal size, a fact which is in keeping with the equality of the load that each ventricle must bear during fetal life. The ECG of the newborn is characterized by the patterns called *right axis deviation* or *right ventricular preponderance*. In actuality such a pattern, seen when both ventricles are anatomically equal, must represent a true balance, or electrical equilibrium.

normal adult pattern indicates not a true balance, but left ventricular preponderance. With this in mind, the electrocardiographic pattern in childhood becomes of diagnostic aid. A continuation of the normal newborn pattern into childhood suggests that the work load of each ventricle, equal in fetal life, has continued unchanged after birth. A shift toward the normal adult "balanced" state in early childhood suggests that the left ventricle has hypertrophied at an accelerated rate as a result of an increased left ventricular work load. Conversely, an increased right ventricular pattern suggests that only the right ventricle has an abnormally increased work load.

Serial ECGs are of great importance not only in diagnosis but in the evaluation of the severity of the condition. Most forms of congenital heart disease do not cause stress during intrauterine life. Only when the fetal circulation is altered by the shift in dependence for gaseous exchange from the placenta to the lungs does stress become manifest. With the passage of time, evidence of hypertrophy of one or both ventricles appears, indicating the presence of increased demand. The rapidity of the electrocardiographic change, furthermore, may serve as an index to the severity of the condition.

It is possible to differentiate the type of stress placed on a ventricle. For example, in the presence of a simple atrial septal defect, the right ventricle has a markedly increased volume of blood flow to accommodate, but resistance to flow from the right ventricle is not usually increased. The typical pattern of the ECG (*diastolic overload of the right ventricle*) is one in which there is a wide QRS complex over the right chest leads associated with a notched R or an RS<sub>R</sub>' pattern, and usually not associated with a marked increase in height of the R wave or an inversion of the T wave. In contrast to this pattern, that of *isolated valvular pulmonic stenosis*, in which the stress placed on the right ventricle is not an increased volume of blood flow, but rather an increased resistance to outflow (*systolic overload*), is characterized by excessively tall R waves over the right chest leads and deep S waves over the left chest leads. When the systolic overload is more severe, inversion of the T wave and depression of the S-T segment are added to the pattern and indicate right ventricular strain.

... all in V<sub>5</sub> as indicative of a balance between the two ventricles. The

The "systolic" and "diastolic overload" patterns have been of definite help in differential diagnosis.

The degree of *right ventricular hypertrophy*, as determined by the ECG, is of value in differential diagnosis, as well as in determining the magnitude of stress placed on the heart. In the presence of pulmonary stenosis with a large ventricular septal defect (*tetralogy of Fallot*), the right ventricle must develop sufficient contractile strength to force blood out through the stenotic pulmonary orifice or through the ventricular defect into the aorta. Because of the ventricular defect, the maximum required work of the right ventricle is merely enough work to overcome systemic resistance. As a consequence, the degree of hypertrophy is not great. On the other hand, when there is *pulmonary stenosis with an intact ventricular septum*, the right ventricle has no escape valve and must overcome the resistance offered by the stenotic pulmonary valve. When stenosis is severe, marked right ventricular hypertrophy of the systolic overload form is present in the ECG. A right ventricular strain pattern is common in this malformation but extremely rare in patients with the typical tetralogy of Fallot.

*Systolic overload of the left ventricle* is characterized by an S in  $V_1$  plus an R in  $V_5$  and  $V_6$  of more than 35 mm. The interval from Q to the peak of the intrinsicoid deflection in the left precordial leads is greater than 0.05 sec. The *left ventricular diastolic overload* pattern is characterized by elevation of the S-T segment in leads facing the left ventricle and an upright, peaked T wave. These patterns are less clear-cut than similar patterns for the right ventricle, and hence, their value in differential diagnosis is less reliable.

Some evidence concerning stress placed on the atria can be obtained from the ECG. A tall, peaked P wave in leads II, III, aVF, and over the right chest leads suggests *right atrial enlargement and hypertrophy*. A notched P wave in leads I, II, aVL, a biphasic P wave in  $V_1$ , and a large P wave with a short P-R interval over the chest leads is evidence of *left atrial enlargement and hypertrophy*.

There are serious pitfalls in the interpretation of the ECG. An abnormal position or unusual rotation of the heart alters the electrocardiographic pattern and may suggest an incorrect

diagnosis. Unusual conduction disturbances may be mistaken for hypertrophy patterns. *Failure of one ventricle* may be associated with a decrease in electrical activity and relative preponderance of the other ventricle in the ECG. Such a pattern has been described in patients with extreme valvular pulmonary stenosis where there is a greatly dilated and thin-walled right ventricle associated with electrocardiographic evidence of left ventricular preponderance.

One point of diagnosis should be strongly emphasized: the clinical findings and laboratory results must all fit together and direct attention toward the correct diagnosis. If there are discrepancies, an explanation for the discrepancies must be given, or the diagnosis may well prove wrong.

## CLASSIFICATION OF CONGENITAL HEART DISEASE

The classification of congenital heart disease presented here is divided into two parts. In part one (outline at beginning of chapter), the classification is based upon the type of defect without reference to whether pulmonary stenosis or pulmonary vascular disease complicates the defect and without reference to the direction of the shunt. In part two (Table 6-1), the factors which control the clinical picture presented by specific malformations are correlated and analyzed. Each group of defects will be discussed first as a unit, with emphasis placed on the alterations in hemodynamics produced by the size of the defect and by varying degrees of pulmonary stenosis or pulmonary vascular disease (right ventricular outflow obstruction). The purpose of doing this is not only to save repetition, but to emphasize that, from the physiologic standpoint, a large patent ductus arteriosus is essentially the same as a large ventricular defect, and a ventricular septal defect associated with severe pulmonary stenosis (tetralogy of Fallot) is similar to a large ventricular defect with advanced pulmonary vascular disease (Eisenmenger's syndrome). Once having established the similarities within each group, the differential diagnostic points can be brought out in a discussion of each specific malformation.

The estimated frequency of clinical syndromes for each defect is presented in Table 6-2.

left ventricle and pulmonary arteries is increased. If the shunt is at the atrial level, the activity of the heart (in the left oblique) is increased anteriorly, but not posteriorly, suggesting that the right ventricle is handling a greater volume of blood than normal. When a patent ductus is present, both the ascending aorta and pulmonary artery may be quite active. If, however, the defect is intracardiac and the shunt from left to right, the aorta appears quiet and smaller than normal. *Tricuspid insufficiency* is suggested by increased activity

normal adult pattern indicates not a true balance, but left ventricular preponderance. With this in mind, the electrocardiographic pattern in childhood becomes of diagnostic aid. A continuation of the normal newborn pattern into childhood suggests that the work load of each ventricle, equal in fetal life, has continued unchanged after birth. A shift toward the normal adult "balanced" state in early childhood suggests that the left ventricle has hypertrophied at an accelerated rate as a result of an increased left ventricular work load. Conversely, an increased right ventricular pattern suggests that only the right ventricle has an abnormally increased work load.

the RAO view.

In contrast to the actively pulsatile pulmonary vessels and heart of a patient with a large left-to-right shunt, *pulmonary stenosis*, *aortic stenosis*, and marked *pulmonary vascular disease* are characterized by a decreased cardiac activity. In patients with an *anomalous left coronary artery* arising from the pulmonary artery or with *endocardial fibroclastosis*, the left ventricle, although large, is strikingly quiet. *Aortic stenosis* is suggested by a delayed and slow pulse wave of the ascending aorta. *Aortic insufficiency* or a left-to-right shunt between the aorta and pulmonary artery is suggested by rapid filling and emptying of the aorta, with an accentuation of the aortic pulsations.

## ELECTROCARDIOGRAM

A few general principles of electrocardiography will be discussed in this chapter; a more detailed analysis may be found in Chap. 5.

In the newborn baby, the right and left ventricles are of equal thickness and equal size, a fact which is in keeping with the equality of the load that each ventricle must bear during fetal life. The ECG of the newborn is characterized by the patterns called *right axis deviation* or *right ventricular preponderance*. In actuality such a pattern, seen when both ventricles are anatomically equal, must represent a true balance, or electrical equality of both ventricles. It is, therefore, an error to consider the normal adult pattern of balanced axis, and in the precordial leads, an S greater than R in lead  $V_1$  and an R in  $V_2$  as indicative of a balance between the two ventricles. The

Serial ECGs are of great importance not only in diagnosis but in the evaluation of the severity of the condition. Most forms of congenital heart disease do not cause stress during intrauterine life. Only when the fetal circulation is altered by the shift in dependence for gaseous exchange from the placenta to the lungs does stress become manifest. With the passage of time, evidence of hypertrophy of one or both ventricles appears, indicating the presence of increased demand. The rapidity of the electrocardiographic change, furthermore, may serve as an index to the severity of the condition.

It is possible to differentiate the type of stress placed on a ventricle. For example, in the presence of a simple *atrial septal defect*, the right ventricle has a markedly increased volume of blood flow to accommodate, but resistance to flow from the right ventricle is not usually increased. The typical pattern of the ECG (*diastolic overload of the right ventricle*) is one in which there is a wide QRS complex over the right chest leads associated with a notched R or an RSR' pattern, and usually not associated with a marked increase in height of the R wave or an inversion of the T wave. In contrast to this pattern, that of *isolated valvular pulmonic stenosis*, in which the stress placed on the right ventricle is not an increased volume of blood flow, but rather an increased resistance to outflow (*systolic overload*),

when the systolic overload is more severe, inversion of the T wave and depression of the S-T segment are added to the pattern and indicate *right ventricular strain*.

## GROUP I: LARGE DEFECTS BETWEEN THE VENTRICLES OR GREAT VESSELS

The left and right ventricle function as a single pump with a common ejectile force, if the defect is functionally large. The volume of blood flow to the systemic and pulmonary circulation, therefore, is totally dependent upon the peripheral resistance in each. The replacement of fluid by air in the alveoli after birth reduces pulmonary resistance. In contrast to the normal circulation of the newborn, the fetal ratio of pulmonary blood flow to the vascular bed is maintained, for every additional patent pulmonary capillary increases the blood flow tapped from the systemic circulation, and pulmonary hypertension persists. The lungs remain as an integral part of the systemic circulation just as in the fetus, alterations in the vascular resistance affect the entire circulation exactly in the same manner as alterations in the kidney, brain, or mesenteric vessels, and yet the lungs, after birth, contain a vascular bed not well supported by surrounding tissue but literally suspended in air. It is small wonder that the pulmonary vascular bed cannot compete with other parts of the circulation without progressive alterations.

There are three lines along which the pulmonary circulation may develop: (1) The reduction of pulmonary resistance following birth leads to a progressive increase in pulmonary blood flow. (2) A balance is maintained between the two circulations by injury and the retention of an efficient vascular tone, sufficient to keep pulmonary vascular resistance on a par with systemic vascular resistance. (3) The sudden decrease in extravascular pressure, combined with the persistence of a high intravascular pressure, produces severe vascular injury, a pulmonary arteritis, and a progressively increasing pulmonary resistance. Thus, in the presence of a large defect, although pulmonary hypertension is retained following birth, the clinical course can be one of (1) low pulmonary resistance, high pulmonary blood flow, and progressive decompensation; (2) balanced flow and relative lack of symptoms until sufficient injury occurs to the pulmonary vessels to elevate pulmonary resistance; or (3) markedly elevated pulmonary resistance, low pulmonary blood flow, right-to-left shunt, and cyanosis.

*Large Defect between the Ventricles or Great Vessels with Minimal Right Ventricular Outflow Obstruction.* With this combination, there is a large left-to-right shunt, a high pulmonary blood flow, and an increased volume of blood returning to the left atrium, causing enlargement of the left side of the heart. The right ventricle is also enlarged since it is forced to generate a pressure equivalent to the systemic.

The signs and symptoms result from left and right heart strain. Dyspnea, fatigability, orthopnea, increased susceptibility to pulmonary infections, and impaired growth and development are common. If heart failure ensues, the most common presenting sign is pulmonary congestion. The peripheral pulses are usually weak. There is a bulge of the left anterior chest and an increased precordial activity. The heart is grossly enlarged, with an active apical impulse located lateral to the midclavicular line in the 5th and 6th left interspace. Murmurs are variable. A systolic murmur, if present, is usually short, early, low pitched, and coarse. A mid-diastolic rumble, heard at the apex, is a common finding. The 2d heart sound at the base is increased in intensity. Rales may be heard over the chest. The liver is enlarged, and there may be peripheral edema.

By fluoroscopic examination, the pulmonary vascular markings appear increased and actively pulsatile. The heart is enlarged, the apex is anteriorly rotated, and the main pulmonary artery segment is less convex than might be expected by the size of the peripheral pulmonary arteries. The apex extends inferiorly and to the left and fails to clear the diaphragm on deep inspiration. In the LAO view, there is posterior rounding, suggesting enlargement of the left ventricle, in the RAO view, the heart impinges on the anterior chest wall, suggesting enlargement of the right side of the heart. The barium-filled esophagus deviates posteriorly in the RAO view, indicating enlargement of the left atrium.

In the ECG, there are wide swinging QRS complexes with a pattern that is neither purely right nor purely left, thereby suggesting biventricular enlargement. A notched P wave may be present in leads II, III, and aVF. In the angiocardigram, there is recirculation of the pulmonary artery and minimal opacification of

TABLE 6-2 ESTIMATED FREQUENCY OF CLINICAL SYNDROMES FOR EACH DEFECT: GROUP 1

| Size of defect | Degree of pulmonic stenosis or pulmonary valve disease | Patent ductus | Aortic septal defect | Single ventricle | Ventricular defect | Tetralogy of Fallot | Truncus | Pseudotruncus | Coarctation with proximal PDA | Coarctation with distal PDA | Single ventricle with transposition | Single ventricle with pulmonary stenosis | IV communis | IV communis with pulmonary stenosis | Biloculate heart | Biloculate heart with pulmonary stenosis | Tricuspid atresia * | Tricuspid atresia with transposition | Transposition with PDA | Transposition with ventricular septal defect | Tauwzig-Bing | Aortic atresia with PDA | Aortic and mitral atresia with PDA | Mitral atresia and ventricular septal defect | Mitral stenosis with PDA | Mitral stenosis with VSD |

\* Pulmonary atresia caused by size of ventricular defect or patent ductus arteriosus.  
Key: 4, most common; 3, common; 2, less common; 1, rare; 0, not seen

the degree of pressure drop. A low-pitched, coarse, and short systolic murmur suggests a minimal pressure differential. A high-pitched jetlike systolic murmur suggests a high pressure differential.

Fluoroscopic evidence of left ventricular and left atrial enlargement is present. Right ventricular enlargement is variable. The ECG suggests more left ventricular enlargement than right. Angiocardiography indicates recanalization of the pulmonary arteries. Cardiac catheterization demonstrates the difference in pressure between the systemic and pulmonary circulations. Otherwise the findings are similar to those of a large defect.

**Medium-sized Defect with Moderate Right Ventricular Outflow Obstruction.** This combination undoubtedly exists but cannot be differentiated from a large defect with moderate outflow tract obstruction. The resistance offered by the pulmonary valve or the small pulmonary vessels is of sufficient magnitude to reduce the volume of pulmonary blood flow to the point where the resistance offered by the defect is no longer manifest and ventricular pressures are equal. The pressure drop occurs across the pulmonary valve or the pulmonary vascular bed and not across the defect. The clinical picture is that of a large defect associated with moderate right ventricular outflow obstruction.

**Moderate-sized Defect with Marked Right Ventricular Outflow Obstruction.** This combination cannot be differentiated from a large defect associated with severe right ventricular outflow obstruction. The resistance offered by the pulmonary arterial bed or pulmonary valve area limits the shunt to a much greater degree than the defect itself. Consequently, the pressures within the right and left side are equal.

**Small Defect with Minimal Right Ventricular Outflow Obstruction.** In this combination, the principal resistance to a left-to-right shunt is the size of the defect. Pressures approach normal in the right side of the heart since the defect offers the chief barrier. The left side of the heart has an increased work load because of the left-to-right shunt, and some left ventricular enlargement may be present. Symptoms are lacking since the volume of shunt is so small that the heart and lungs are not sufficiently embarrassed. Physical examination reveals a well-developed and well-nourished individual with normal peripheral pulses, no

bulge to the left chest, minimal or absent cardiac enlargement, and normal precordial activity. The outstanding findings are auscultatory. Since pressures in both circulations are normal, the flow of blood across the defect is at high velocity, causing a loud, long, high-pitched systolic murmur heard best along the left sternal border in the 4th and 5th left interspace. Evidence of failure is not present. Fluoroscopic examination reveals a normal heart or one with minimal left-sided enlargement. The pulmonary vascular markings are slightly increased and overly pulsatile. The ECG usually is normal. Some evidence of recanalization of the pulmonary circulation may be present in the angiogram. Cardiac catheterization establishes the presence of normal pressures in the two sides of the heart, and a rise in oxygen content is found at the level of the defect.

**Small Defect with Moderate Right Ventricular Outflow Obstruction.** A small defect associated with moderate pulmonary stenosis is an unusual combination. A small defect associated with moderate pulmonary vascular disease is seen occasionally in older patients in whom the available pulmonary vascular bed has been reduced by pulmonary parenchymal disease. The increased work load is primarily on the right ventricle. Exertional dyspnea is common. Cyanosis may appear with exercise. Physical findings are dependent upon the degree of pulmonary stenosis or pulmonary vascular disease. Since the shunt is reduced by the pulmonary resistance and not by the defect, the murmur arising from the defect is not present. A loud, long, high-pitched systolic murmur is present if the increased pulmonary resistance is at the valve.

**Small Defect with Marked Right Ventricular Outflow Obstruction.** This combination is very rare. The degree of resistance in the pulmonary vascular bed or at the pulmonary valve places a heavy load on the right side of the heart which, in this instance, cannot be reduced sufficiently by the right-to-left shunt through the excessively small defect. The right side of the heart is enlarged, perhaps markedly so. Signs and symptoms are dyspnea, marked fatigability, occasional spells of paroxysmal dyspnea, cyanosis that may be marked, and evidence of right heart failure. On physical examination, the findings are those of isolated pulmonary obstruction with intact ventricular sep-

TABLE 6-2 ESTIMATED FREQUENCY OF CARDIAC SYNDROMES FOR EACH DEFECT: GROUP 1

the degree of pressure drop. A low-pitched, coarse, and short systolic murmur suggests a minimal pressure differential. A high-pitched jetlike systolic murmur suggests a high pressure differential.

Fluoroscopic evidence of left ventricular and left atrial enlargement is present. Right ventricular enlargement is variable. The ECG suggests more left ventricular enlargement than right. Angiocardiography indicates reopacification of the pulmonary arteries. Cardiac catheterization demonstrates the difference in pressure between the systemic and pulmonary circulations. Otherwise the findings are similar to those of a large defect.

**Medium-sized Defect with Moderate Right Ventricular Outflow Obstruction.** This combination undoubtedly exists but cannot be differentiated from a large defect with moderate outflow tract obstruction. The resistance offered by the pulmonary valve or the small pulmonary vessels is of sufficient magnitude to reduce the volume of pulmonary blood flow to the point where the resistance offered by the defect is no longer manifest and ventricular pressures are equal. The pressure drop occurs across the pulmonary valve or the pulmonary vascular bed and not across the defect. The clinical picture is that of a large defect associated with moderate right ventricular outflow obstruction.

**Moderate-sized Defect with Marked Right Ventricular Outflow Obstruction.** This combination cannot be differentiated from a large defect associated with severe right ventricular outflow obstruction. The resistance offered by the pulmonary arterial bed or pulmonary valve area limits the shunt to a much greater degree than the defect itself. Consequently, the pressures within the right and left side are equal.

**Small Defect with Minimal Right Ventricular Outflow Obstruction.** In this combination, the principal resistance to a left-to-right shunt is the size of the defect. Pressures approach normal in the right side of the heart since the defect offers the chief barrier. The left side of the heart has an increased work load because of the left-to-right shunt, and some left ventricular enlargement may be present. Symptoms are lacking since the volume of shunt is so small that the heart and lungs are not sufficiently embarrassed. Physical examination reveals a well-developed and well-nourished individual with normal peripheral pulses, no

bulge to the left chest, minimal or absent cardiac enlargement, and normal precordial activity. The outstanding findings are auscultatory. Since pressures in both circulations are normal, the flow of blood across the defect is at high velocity, causing a loud, long, high-pitched systolic murmur heard best along the left sternal border in the 4th and 5th left inter-space. Evidence of failure is not present. Fluoroscopic examination reveals a normal heart or one with minimal left-sided enlargement. The pulmonary vascular markings are slightly increased and overly pulsatile. The ECG usually is normal. Some evidence of reopacification of the pulmonary circulation may be present in the angiocardiogram. Cardiac catheterization establishes the presence of normal pressures in the two sides of the heart, and a rise in oxygen content is found at the level of the defect.

**Small Defect with Moderate Right Ventricular Outflow Obstruction.** A small defect associated with moderate pulmonary stenosis is an unusual combination. A small defect associated with moderate pulmonary vascular disease is seen occasionally in older patients in whom the available pulmonary vascular bed has been reduced by pulmonary parenchymal disease. The increased work load is primarily on the right ventricle. Exertional dyspnea is common. Cyanosis may appear with exercise. Physical findings are dependent upon the degree of pulmonary stenosis or pulmonary vascular disease. Since the shunt is reduced by the pulmonary resistance and not by the defect, the murmur arising from the defect is not present. A loud, long, high-pitched systolic murmur is present if the increased pulmonary resistance is at the valve.

**Small Defect with Marked Right Ventricular Outflow Obstruction.** This combination is very rare. The degree of resistance in the pulmonary vascular bed or at the pulmonary valve places a heavy load on the right side of the heart which, in this instance, cannot be reduced sufficiently by the right-to-left shunt through the excessively small defect. The right side of the heart is enlarged, perhaps markedly so. Signs and symptoms are dyspnea, marked fatigability, occasional spells of paroxysmal dyspnea, cyanosis that may be marked, and evidence of right heart failure. On physical examination, the findings are those of isolated pulmonary obstruction with intact ventricular sep-

the aorta. Catheterization findings are those of a large left-to-right shunt at or distal to the ventricles, minimal or absent right-to-left shunt, equal systolic pressures in the right ventricle and brachial artery, and elevated pulmonary wedge pressures.

**Large Defect with Moderate Right Ventricular Outflow Obstruction.** When there is a moderate obstruction to right ventricular outflow, the resistance to blood flow through the lungs approximates the resistance to blood flow through the systemic circulation, and flows are essentially equal. The left side of the heart is normal. The right ventricle is increased in size because it must generate a pressure equal to that of the left ventricle. Signs and symptoms are mild or absent. There may be mild exertional dyspnea and, with severe exercise, some degree of cyanosis. Growth and development are within normal limits. On physical examination, the peripheral pulses are normal. There is no bulge of the precordium, and the heart is approximately normal in size. Precordial activity may be increased. There may be a short early-systolic murmur. There is no evidence of cardiac failure.

On fluoroscopy, the left atrium and the left ventricle are normal. In the oblique views, there is a suggestion of right ventricular enlargement. In the ECG, there is right axis deviation and evidence of moderate right ventricular hypertrophy. An angiocardiogram may fail to demonstrate any shunt, or there may be reopacification of the pulmonary artery and early visualization of the aorta, indicating both a left-to-right and right-to-left shunt. An equal right ventricular and brachial artery systolic pressure is demonstrated by catheterization. There is usually some degree of arterial unsaturation and a slight increase of right ventricular blood oxygen content. Pulmonary wedge pressures are normal.

**Large Defect with Severe Right Ventricular Outflow Obstruction.** When this combination is present, the findings are due to a markedly reduced pulmonary blood flow. The left ventricle is normal in size. The right ventricle is increased in size because of the increase in resistance to ventricular outflow. Symptoms include cyanosis, exertional dyspnea, and marked fatigability. Growth and development are retarded. Cyanosis and clubbing are present. Peripheral pulses are normal. The right ventricle may appear

slightly enlarged. Murmurs are variable, depending upon the exact nature of the defect. The chest is clear. Evidence of cardiac failure is absent. On fluoroscopy, there is evidence of right ventricular enlargement. In the ECG, there is right axis deviation and right ventricular hypertrophy, without evidence of left ventricular hypertrophy. An angiocardiogram reveals early opacification of the aorta and delayed filling of the pulmonary arterial tree. Catheterization findings are those of a common systolic pressure in the right ventricle and brachial artery and marked arterial unsaturation.

**Moderate-sized Defect with Minimal Right Ventricular Outflow Obstruction.** A moderate-sized defect is defined as one large enough to permit a sufficient volume of blood flow to utilize most of the available pulmonary vascular bed, yet small enough to limit blood flow by its size. Thus, the volume of pulmonary blood flow is controlled by both the resistance offered by the pulmonary circulation and the resistance offered by the defect. The medium-sized defect associated with minimal pulmonary stenosis or pulmonary vascular disease causes a left-to-right shunt since the resistance of the lungs and of the defect is significantly less than the resistance of the systemic circulation.

The signs and symptoms differ only in degree from those of a large defect associated with minimal outflow obstruction. The left side of the heart is enlarged because of increased return of blood to the left atrium and left ventricle. The degree of right-sided enlargement varies directly with right ventricular pressure. Symptoms are fatigability, exertional dyspnea, and susceptibility to pulmonary infections.

The difference in cardiac findings between this group and the group with a large defect depends upon the pressure drop across the defect. Examination of the precordium may suggest that the left ventricle is performing more work than the right. There is a forceful and diffuse apical impulse which is more active than the right ventricular impulse close to the sternum. The apex is lower and more to the left, indicating left ventricular enlargement. There is a systolic murmur, which is caused by rapid blood flow through the defect. The quality and duration of the murmur depend upon

tricular defect (maximal in early systole). The pulmonary 2d sound is split and loud. A diastolic murmur, faint and blowing and decrescendo in type, may be present along the left sternal border. A mid-diastolic rumble resulting from a large return of blood to the left ventricle may be present at the apex. On fluoroscopy, the presence of both an enlarged hyperactive ascending aorta and pulmonary artery suggests that the shunt occurs distal to the ventricles. Angiocardiogram in the left oblique view may suggest the presence of an intermittent right-to-left shunt by opacification of the descending aorta as well as reopacification of the pulmonary artery. Cardiac catheterization reveals a high pulmonary artery pressure and a rise in the oxygen content distal to the pulmonary valve. The diagnostic value of the oxygen content rise may be obscured by the presence of pulmonary insufficiency, leading to a rise in oxygen content in the outflow tract of the right ventricle. The most efficient differential diagnostic test for this syndrome is a retrograde aortogram. Contrast medium injected under pressure into the left brachial artery in a retrograde manner will opacify the pulmonary arteries immediately.

**Large Patent Ductus Arteriosus with Marked Pulmonary Vascular Disease.** This, the reverse ductus, is usually not seen until late in life. The flow is from right to left because of the high pulmonary resistance. Differential diagnostic findings are related to the position of the shunt since the ductus communicates with the aorta at, or just distal to, the origin of the left subclavian artery. Cyanosis of the lower extremities and left hand is pathognomonic. If the shunt is small in magnitude, no cyanosis is present, but simultaneous oxygen determinations from the right brachial and femoral arteries reveal a lower saturation in the femoral artery than in the brachial. Angiocardiogram in the left oblique position may suggest early opacification of the descending aorta.

**THERAPY.** Therapy for the typical variety of patent ductus arteriosus is, with few exceptions, surgical closure. When the ductus is large and pulmonary vascular disease moderate or mild, early closure is mandatory, for only in this way can a progressive increase in pulmonary resistance be prevented. Furthermore, when left heart failure is present, closure

can be lifesaving. The question of closure of a reverse ductus is difficult. Closure is indicated if it can be established that the right-to-left shunt through the defect can be eliminated or greatly reduced by breathing 100 per cent oxygen or if the shunt, though bidirectional, is predominantly left to right.

**Moderate Aortic Septal Defect with Moderate Pulmonary Vascular Disease.** In this malformation, there is a communication between the aorta and pulmonary artery just distal to the aortic and pulmonary valve. The distinguishing diagnostic features of a moderate-sized septal defect are few. A systolic murmur, maximal in the 3d left interspace and extending slightly into diastole, is suggestive. The first portion of the ascending aorta and main pulmonary artery is usually markedly dilated. Cardiac catheterization is of little help unless the catheter can be passed through the defect into the aorta and innominate artery, thus distinguishing the defect from a patent ductus arteriosus. However, one must be sure that the catheter did not pass through a ventricular defect to the aorta rather than through an aortic septal defect. Angiocardiography will reveal opacification of the ascending aorta as well as the descending aorta, which serves to distinguish this defect from a reverse ductus. To differentiate this defect from a ventricular defect, a retrograde aortogram, done through the right brachial artery with the right carotid momentarily occluded, will result in a heavy flow of contrast medium into the pulmonary circulation without opacification of the ventricles.

**Small Aortic Septal Defect with Minimal Pulmonary Vascular Disease.** The findings are those of a patent ductus except that the continuous murmur is audible lower and more to the right than is usual with a patent ductus. The murmur transmits widely. The differential diagnosis is best made with retrograde aortography, for with an aortic septal defect, when the contrast medium is introduced into the left brachial artery, the lungs will not be opacified. Contrast medium injected into the right brachial artery may opacify the pulmonary vessels but not the ventricles.

**THERAPY.** Correction of an aortic septal defect, if it is to be successful, must be performed during childhood, for pulmonary vascular disease tends to develop early. Surgical closure

tum rather than those of an extreme tetralogy of Fallot. The right ventricle is greatly enlarged. There is a precordial bulge, but the precordium is quiet. There is a loud, high-pitched, and jetlike systolic murmur if the pulmonary obstruction is valvular or infundibular. A systolic murmur arising from the right-to-left shunt through the defect may also be present. The lungs are clear. There is evidence of right-sided congestive failure, with enlargement of the liver and peripheral edema. The liver may pulsate with a strong presystolic pulsation, indicating marked right atrial hypertrophy, and occasionally with systolic pulsations, indicating tricuspid insufficiency. Fluoroscopic examination reveals a markedly enlarged right ventricle and right atrium. Peripheral lung fields appear clear. The left side of the heart is normal. The ECG reveals pure right-sided hypertrophy of the systolic overload type, which is frequently extreme and associated with right heart strain. Angiocardiography reveals a delayed passage of contrast medium through the pulmonary bed. There may be evidence of right-to-left shunt with early opacification of the aorta. Cardiac catheterization findings are those of a markedly increased right ventricular pressure, increased right atrial pressure, and a significant degree of arterial oxygen unsaturation. Venous oxygen saturation in the right side of the heart is low, indicating a low systemic blood flow.

## ANALYSIS OF SPECIFIC MALFORMATIONS

In Table 6-2 are estimated the relative incidence of the size of defect and degree of pulmonary stenosis or pulmonary vascular disease found in each specific malformation. Conditions associated with pulmonary stenosis of varying degrees have been separated from those associated with pulmonary vascular disease according to the difference in frequency. Thus, the most common form of patent ductus arteriosus is a small ductus associated with minimal or absent pulmonary vascular disease. In contrast, the most common form of tetralogy of Fallot is a large or medium-sized ventricular defect associated with marked pulmonary stenosis. In the discussion of each specific malformation, the most common form will be discussed first, and emphasis will be placed on the distinguishing diagnostic points separating

one malformation from another having a comparable defect size and a similar pulmonary resistance.

**Small Patent Ductus Arteriosus with Minimal or Absent Pulmonary Vascular Disease.** The usual patent ductus arteriosus is small, 4 to 8 mm in internal diameter and 1 to 2 cm long, connecting the left pulmonary artery and the aorta just distal to the origin of the left subclavian. The volume of the shunt is sharply limited by the ductal size. Pulmonary pressure is within normal limits. Positive physical findings are late in appearing, so that the patient is usually referred during the second year of life or later. The distinctive physical findings relate to the continuous draining of blood from the aorta into the pulmonary circulation. There is a high systemic pressure with an increased systolic and a definitely lowered diastolic pressure. Peripheral pulses tend to be bounding in nature. There is a continuous murmur, maximal in the 2d left interspace, well heard in the 1st, with the diastolic component fading in the 3d and disappearing in the 4th interspace. This reaches its greatest intensity in midsystole and extends throughout diastole. The murmur is

... and the neck, and is faintly heard in the back. A mid-diastolic rumble at the apex is evidence of increased blood flow through the mitral valve. On fluoroscopy, the main pulmonary artery segment tends to be full and there is increased activity of both the ascending aorta and the pulmonary artery. In the angiocardiogram, an irregularity of the aorta at the level of the ductus is present, a filling defect of the pulmonary artery may be noticed, and there may be reopacification of the pulmonary circulation. Cardiac catheterization reveals a rise in the oxygen content of the blood distal to the pulmonary valve.

**Large Patent Ductus Arteriosus with Minimal or Moderate Pulmonary Vascular Disease.** This entity is not uncommon during early childhood. A high pulse pressure with a bounding and collapsing pulse may be present. Instead of the continuous murmur heard with a small ductus, the only murmur present is a low-pitched, coarse systolic murmur, located in the 2d left inter-

years of age. With this syndrome, the important differential diagnostic point is the localization of the pulmonary obstruction. Frequently, no murmur is present, suggesting pulmonary vascular disease rather than valvular pulmonary stenosis. When present, the murmur is frequently low-pitched and coarse and does not suggest a high pressure gradient across the defect or valve. The presence of a loud split 2d heart sound and a diastolic decrescendo murmur along the left sternal border suggests pulmonary hypertension and insufficiency, thus placing the obstruction in the distal pulmonary arteries. On fluoroscopic examination, the main pulmonary artery and the peripheral pulmonary arteries may be abnormally large. Angiocardiographic studies fail to demonstrate an infundibular chamber and infundibular or valvular stenosis. A sudden change from a large to a remarkably small lumen may be noted in the peripheral pulmonary vessels. Occasionally, the differential diagnosis between this syndrome and one associated with pulmonary valvular stenosis cannot be made unless catheterization of the right ventricle and pulmonary artery demonstrates the presence or absence of a pressure gradient across the valve.

**Moderate-sized Ventricular Defect with Minimal to Moderate Pulmonary Vascular Disease.** The medium-sized defect may be indistinguishable from a large ventricular defect because of the size of the available vascular bed in the small infant. However, with growth of the child and increase in cardiac output without a comparable increase in the size of the defect, the point is reached when the total available vascular bed no longer is being utilized. The resistance offered by the defect limits flow, and a pressure differential between the left and right ventricle appears. A loud and long systolic murmur along the left sternal border, maximal in the 4th interspace and associated with a thrill, strongly suggests the presence of a pressure differential from left to right ventricle. This finding is born out by direct pressure measurements during cardiac catheterization.

**Small Ventricular Defect with Minimal Pulmonary Vascular Disease.** This condition, the classic *Roger's disease*, is much less frequent than previously thought. The significant diagnostic finding is the presence of a long, loud, high-pitched systolic murmur associated with

a strong systolic thrill along the left sternal border, maximal in the 4th and 5th interspace. The murmur is jetlike in quality and suggests a marked pressure differential with a high-velocity blood flow across a defect. The catheterization findings are those of an increase in blood oxygen content in the right ventricular outflow tract associated with a normal right ventricular pressure.

A wide range exists between the small defect and the medium-sized defect. The larger the defect, the greater the shunt, until the point is reached where a major portion of the pulmonary vascular bed is utilized and pulmonary artery pressure, even at rest, is elevated. The increasing shunt is paralleled by increasing left ventricular work and by the increasing size of both left ventricle and left atrium. When the point is reached where pulmonary artery pressure rises, the work of the right ventricle is increased and evidence of right ventricular hypertrophy appears.

**THERAPY** As already pointed out, it is common to see patients with large ventricular septal defects who demonstrate successive syndromes. The first, appearing within a few weeks after birth, is that of *high-output failure*. The second, which appears in the second and third year of life, is that of *increasing pulmonary resistance*, decreasing pulmonary blood flow, and gradual clinical improvement. The third (*Eisenmenger's syndrome*) is associated with marked pulmonary vascular disease and is the end result unless therapy removes the stimulus toward progressive vascular disease.

During the first phase of high-output cardiac failure, successful closure using an extracorporeal circulation has been done, but this procedure carries a high risk. The palliative approach of creating pulmonary stenosis may be the operation of choice in the very small infant. Narrowing the pulmonary artery by 75 per cent of its cross-sectional area produces a significant barrier and reduces pulmonary blood flow to between one and two times systemic blood flow. Pulmonary artery pressure falls, thus removing the stimulus toward progressive vascular disease. By this method, congestive failure can be successfully treated, and growth and development become normal. In time, the risk of corrective surgery becomes less. Such a course also may be indicated in the presence of a medium-sized ventricular defect with min-

tum rather than those of an extreme tetralogy of Fallot. The right ventricle is greatly enlarged. There is a precordial bulge, but the precordium is quiet. There is a loud, high-pitched, and jetlike systolic murmur if the pulmonary obstruction is valvular or infundibular. A systolic murmur arising from the right-to-left shunt through the defect may also be present. The lungs are clear. There is evidence of right-sided congestive failure, with enlargement of the liver and peripheral edema. The liver may pulsate with a strong presystolic pulsation, indicating marked right atrial hypertrophy, and occasionally with systolic pulsations, indicating tricuspid insufficiency. Fluoroscopic examination reveals a markedly enlarged right ventricle and right atrium. Peripheral lung fields appear clear. The left side of the heart is normal. The ECG reveals pure right-sided hypertrophy of the systolic overload type, which is frequently extreme and associated with right heart strain. Angiocardiography reveals a delayed passage of contrast medium through the pulmonary bed. There may be evidence of right-to-left shunt with early opacification of the aorta. Cardiac catheterization findings are those of a markedly increased right ventricular pressure, increased right atrial pressure, and a significant degree of arterial oxygen unsaturation. Venous oxygen saturation in the right side of the heart is low, indicating a low systemic blood flow.

### ANALYSIS OF SPECIFIC MALFORMATIONS

In Table 6-2 are estimated the relative incidence of the size of defect and degree of pulmonary stenosis or pulmonary vascular disease found in each specific malformation. Conditions associated with pulmonary stenosis of varying degrees have been separated from those associated with pulmonary vascular disease according to the difference in frequency. Thus, the most common form of patent ductus arteriosus is a small ductus associated with minimal or absent pulmonary vascular disease. In contrast, the most common form of tetralogy of Fallot is a large or medium-sized ventricular defect associated with marked pulmonary stenosis. In the discussion of each specific malformation, the most common form will be discussed first, and emphasis will be placed on the distinguishing diagnostic points separating

one malformation from another having a comparable defect size and a similar pulmonary resistance.

**Small Patent Ductus Arteriosus with Minimal or Absent Pulmonary Vascular Disease.** The usual patent ductus arteriosus is small, 4 to 8 mm in internal diameter and 1 to 2 cm long, connecting the left pulmonary artery and the aorta just distal to the origin of the left subclavian. The volume of the shunt is sharply limited by the ductal size. Pulmonary pressure is within normal limits. Positive physical findings are late in appearing, so that the patient is usually referred during the second year of life or later. The distinctive physical findings relate to the continuous draining of blood from the aorta into the pulmonary circulation. There is a high systemic pressure with an increased systolic and a definitely lowered diastolic pressure. Peripheral pulses tend to be bounding in nature. There is a continuous murmur, maximal in the 2d left interspace, well heard in the 1st, with the diastolic component fading in the 3d and disappearing in the 4th interspace. This reaches its greatest intensity in midsystole and extends throughout diastole. The murmur is typically rumbling and coarse. It is transmitted laterally toward the left axilla, is not well transmitted into the neck, and is faintly heard in the back. A mid-diastolic rumble at the apex is evidence of increased blood flow through the mitral valve. On fluoroscopy, the main pulmonary artery segment tends to be full and there is increased activity of both the ascending aorta and the pulmonary artery. In the angiocardigram, an irregularity of the aorta at the level of the ductus is present, a filling defect of the pulmonary artery may be noticed, and there may be reopacification of the pulmonary circulation. Cardiac catheterization reveals a rise in the oxygen content of the blood distal to the pulmonary valve.

**Large Patent Ductus Arteriosus with Minimal or Moderate Pulmonary Vascular Disease**

The pulse may be present. Instead of the continuous murmur heard with a small ductus, the only murmur present is a low-pitched, coarse systolic murmur, located in the 2d left interspace, which occasionally overlaps into diastole. It is maximal in midsystole, which distinguishes it from the murmur of a ven-

midline, and if the pulmonary artery is intubated, the origin of the pulmonary artery may be demonstrated in the midline and posteriorly. Unfortunately, it is frequently impossible to catheterize a great vessel. The remaining laboratory findings suggest the presence of a ventricular defect usually of medium or large size.

**THERAPY.** The significant lesion to be treated is the ventricular defect, and the same criteria of management apply to this malformation as to the uncomplicated ventricular defect. No special treatment for the transposition is necessary.

**Tetralogy of Fallot.** In this malformation, the ventricular septal defect is associated with infundibular or valvular pulmonary stenosis, an overriding aorta, and right ventricular hypertrophy. The clinical picture is governed by the size of the ventricular defect and the degree of stenosis. With rare exceptions, the degree of overriding of the aorta does not affect the patient's symptoms.

**Tetralogy of Fallot, Large Defect with Moderate Pulmonary Stenosis.** This combination produces dyspnea and cyanosis early in childhood. The diagnostic findings are a *systolic thrill* in the 2d and 3d left interspace associated with a long, high-pitched *systolic murmur*, which is well transmitted over the lung fields. The quality of the murmur suggests a high pressure gradient. The *pulmonary 2d sound is usually pure and soft*. However, because of dextroposition of the aorta, the 2d heart sound may be increased at the left of the sternum (the area where the pulmonary 2d sound is usually heard). Diastole is clear. Evidence of failure is lacking. *Fluoroscopic examination* presents a rather characteristic picture: a small horizontally positioned heart with a blunt, upturned apex which clears the diaphragm is seen in the PA projection. The *main pulmonary artery segment is concave*. The right and left pulmonary arteries are normal in size. The *peripheral vascular markings are usually decreased*. Minimal pulsations may be seen in the pulmonary vessels. A barium swallow indicates the position of the aortic arch. In about 25 per cent of patients with a tetralogy of Fallot, there is a *right aortic arch*, which deviates the esophagus toward the left in the PA projection and posteriorly in the LAO projection. With a left aortic arch, the esophagus is deviated to the right at the level

of the arch and posteriorly in the RAO position. Occasionally, there is a bulge of the left upper cardiac salient or at a little below the level of the main pulmonary artery segment. Pulsations in this area are fairly marked and may appear opposite the ventricular pulsations. This *bulge represents an infundibular chamber* between the area of stenosis and the pulmonary valve.

When the pulmonary artery is catheterized, a drop in pressure (gradient of pressure) is demonstrated from the systemic right ventricle to the infundibular area or pulmonary artery. Pulmonary artery pressure is normal. A small left-to-right shunt at the ventricular level may be present, and there is arterial unsaturation. It may be possible to distinguish with an angiocardigram whether stenosis is predominantly infundibular or valvular.

**Tetralogy of Fallot, Large Defect with Severe Pulmonary Stenosis or Pulmonary Atresia (Pseudotruncus Arteriosus).** When this combination is present, the major portion of pulmonary blood flow reaches the lungs through collateral vessels arising from the bronchial vessels, the subclavian arteries, the internal mammaries, and occasionally from below the diaphragm. Symptoms are those of extreme fatigability, dyspnea, and cyanosis. In infancy, many patients are subject to repeated spells of *paroxysmal dyspnea*, characterized by a sudden unexplained increase in cyanosis, gasping irregular respirations, a cry of severe pain, and at times, *loss of consciousness*. On physical examination, the cyanosis is marked. A *systolic murmur*, which is high in pitch and moderately long, is heard loudest in the 2d and 3d left interspace. Occasionally no murmur is present, suggesting either that there is an atresia of the outflow tract of the right ventricle, or that severe polycythemia has increased blood viscosity and decreased the turbulence of blood as it passes through the area of stenosis, therefore making a previously audible murmur inaudible. In the severely cyanotic patient, a careful examination for extracardiac murmurs should be made for, not infrequently, a *soft, continuous humming murmur* will be heard over the back, in the axilla, and to the right and left of the sternum anteriorly. This murmur arises from large tortuous collateral vessels and not from a patent ductus arteriosus. Its presence suggests pulmonary atresia. The 2d heart sound at the base of the heart is pure.

should be performed, using extracorporeal circulation because of the technical difficulty of maintaining coronary circulation and separating the two great vessels by sharp dissection

**True Truncus Arteriosus, Large Pulmonary Arteries with Moderate Pulmonary Vascular Disease.** This rare malformation is an extension of the aortic septal defect to include a common aortic and pulmonic valve and a defect of the ventricular membranous septum. Above the common aortic-pulmonic valve arises a single vessel which branches rapidly, giving off a right and left pulmonary artery and continues as the aorta. Blood flow to the lungs is entirely regulated by the degree of pulmonary vascular disease. In early infancy, pulmonary resistance may be minimal and the occurrence of severe congestive failure is not at all unusual. The development of pulmonary vascular disease is rapid, however, and the patient who survives the period of failure passes quickly to the stage of cyanosis.

The differential diagnosis is obviously difficult. The murmurs are extremely variable. The turbulence created by the stream of blood from the right and left ventricles meeting in a common vessel causes a low-pitched, coarse systolic murmur. The common aortic-pulmonic valve is not infrequently incompetent, resulting in a decrescendo diastolic murmur heard along both sides of the sternum and a high pulse pressure. These murmurs must be distinguished from the continuous murmur heard in the pseudotruncus arteriosus, where blood flow to the lungs is through collateral vessels arising from the aorta. Fluoroscopic examination may reveal an aneurysmal dilatation of the ascending aorta with markedly enlarged right and left pulmonary arteries and a concave main pulmonary segment. Cardiac catheterization is of little differential diagnostic value. If the course of the catheter is analyzed carefully, its passage into a pulmonary artery arising from the aorta may be demonstrated. Angiocardiography reveals equally rapid opacification of the pulmonary vessels and aorta and an absence of a distinct main pulmonary artery.

Correction of this malformation is possible. However, the chances of obtaining a normally functioning aortic and pulmonic valve are poor, and at the present time, our approach is to produce stenosis of the right and left pulmonary

arteries to control congestive failure and remove the stimulus to progressive pulmonary vascular disease.

**Large Ventricular Septal Defect with Minimal or Moderate Pulmonary Vascular Disease.** In this malformation, there is a defect between the two ventricles, usually involving the membranous septum and occasionally the muscular septum. The defect lies close to the origin of the aorta and may involve the septal leaflet of the aortic valve, thus complicating the hemodynamic changes by the addition of aortic insufficiency. Under the age of 2 years, the most common syndrome is a large ventricular defect associated with mild to moderate pulmonary vascular disease. Death from high-output cardiac failure is frequent. A systolic murmur is present, usually short, low-pitched, coarse, and maximal in the 3d and 4th left interspace close to the sternum, moderately well transmitted to the lungs, but not to the neck. There is a loud, split 2d heart sound frequently followed by an early diastolic murmur in decrescendo. A mid-diastolic rumble at the apex suggests increased flow through the mitral valve. Under the fluoroscope, the ascending aorta is small and quiet, in contrast to the aorta which is observed when a large patent ductus is present. Cardiac catheterization may reveal an increase in oxygen content in the inflow tract of the right ventricle, which serves to differentiate it from a patent ductus, since with the latter one would not expect a rise in oxygen in the inflow tract even with severe pulmonic insufficiency. More commonly, the oxygen rise is found in the outflow tract of the right ventricle. A further increase in oxygen content may be found in the pulmonary artery because of streamlining of blood from the left ventricle. Angiocardiography may be a diagnostic aid. Early filling of the left ventricle, but not the left atrium, would indicate shunt from right to left at the ventricular level. Reopacification of the right ventricle and pulmonary arteries indicates a left-to-right shunt at the ventricular level. However, the surest way of ruling out a patent ductus arteriosus in the infant is the use of retrograde aortography.

**Large Ventricular Septal Defect with Marked Pulmonary Vascular Disease.** This condition is infrequent before the age of 4 but becomes increasingly more common after 10

midline, and if the pulmonary artery is intubated, the origin of the pulmonary artery may be demonstrated in the midline and posteriorly. Unfortunately, it is frequently impossible to catheterize a great vessel. The remaining laboratory findings suggest the presence of a ventricular defect usually of medium or large size.

**THERAPY.** The significant lesion to be treated is the ventricular defect, and the same criteria of management apply to this malformation as to the uncomplicated ventricular defect. No special treatment for the transposition is necessary.

**Tetralogy of Fallot.** In this malformation, the ventricular septal defect is associated with infundibular or valvular pulmonary stenosis, an overriding aorta, and right ventricular hypertrophy. The clinical picture is governed by the size of the ventricular defect and the degree of stenosis. With rare exceptions, the degree of overriding of the aorta does not affect the patient's symptoms.

**Tetralogy of Fallot, Large Defect with Moderate Pulmonary Stenosis.** This combination produces dyspnea and cyanosis early in childhood. The diagnostic findings are a *systolic thrill* in the 2d and 3d left interspace associated with a long, high-pitched *systolic murmur*, which is well transmitted over the lung fields. The quality of the murmur suggests a high pressure gradient. The *pulmonary 2d sound is usually pure and soft*. However, because of dextroposition of the aorta, the 2d heart sound may be increased at the left of the sternum (the area where the pulmonary 2d sound is usually heard). Diastole is clear. Evidence of failure is lacking. *Fluoroscopic examination* presents a rather characteristic picture: a small horizontally positioned heart with a blunt, upturned apex which clears the diaphragm is seen in the PA projection. The *main pulmonary artery segment is concave*. The right and left pulmonary arteries are normal in size. The *peripheral vascular markings are usually decreased*. Minimal pulsations may be seen in the pulmonary vessels. A barium swallow indicates the position of the aortic arch. In about 25 per cent of patients with a tetralogy of Fallot, there is a *right aortic arch*, which deviates the esophagus toward the left in the PA projection and posteriorly in the LAO projection. With a left aortic arch, the esophagus is deviated to the right at the level

of the arch and posteriorly in the RAO position. Occasionally, there is a bulge of the left upper cardiac salient or at a little below the level of the main pulmonary artery segment. Pulsations in this area are fairly marked and may appear opposite the ventricular pulsations. This *bulge represents an infundibular chamber* between the area of stenosis and the pulmonary valve.

When the pulmonary artery is catheterized, a drop in pressure (gradient of pressure) is demonstrated from the systemic right ventricle to the infundibular area or pulmonary artery. Pulmonary artery pressure is normal. A small left-to-right shunt at the ventricular level may be present, and there is arterial unsaturation. It may be possible to distinguish with an angiocardigram whether stenosis is predominantly infundibular or valvular.

**Tetralogy of Fallot, Large Defect with Severe Pulmonary Stenosis or Pulmonary Atresia (Pseudotruncus Arteriosus).** When this combination is present, the major portion of pulmonary blood flow reaches the lungs through collateral vessels arising from the bronchial vessels, the subclavian arteries, the internal mammaries, and occasionally from below the diaphragm. Symptoms are those of extreme fatigability, dyspnea, and cyanosis. In infancy, many patients are subject to repeated spells of *paroxysmal dyspnea*, characterized by a sudden unexplained increase in cyanosis, gasping irregular respirations, a cry of severe pain, and at times, *loss of consciousness*. On physical examination, the cyanosis is marked. A *systolic murmur*, which is high in pitch and moderately long, is heard loudest in the 2d and 3d left interspace. Occasionally no murmur is present, suggesting either that there is an atresia of the outflow tract of the right ventricle, or that severe polycythemia has increased blood viscosity and decreased the turbulence of blood as it passes through the area of stenosis, therefore making a previously audible murmur inaudible. In the severely cyanotic patient, a careful examination for extracardiac murmurs should be made for, not infrequently, a *soft, continuous humming murmur* will be heard over the back, in the axilla, and to the right and left of the sternum anteriorly. This murmur arises from large tortuous collateral vessels and not from a patent ductus arteriosus. Its presence suggests pulmonary atresia. The 2d heart sound at the base of the heart is pure.

mal pulmonary vascular disease, a large left-to-right shunt, and left heart failure

In older patients with moderate or marked pulmonary vascular disease associated with a large or medium-sized ventricular defect, the decision concerning therapy is based on the magnitude and exact nature of the pulmonary vascular changes. The principal question to be answered is whether the shunt occurring through the defect is predominantly left to right or right to left. If it is *predominantly left to right*, closure of the defect should result in a drop in pulmonary artery pressure, thus increasing the chances of recovery. A significant drop in pulmonary vascular resistance can be anticipated. If, on the other hand, the shunt is *predominantly right to left*, closure of the defect will result in increased pulmonary blood flow against a high vascular resistance, leading to an increase in pulmonary artery pressure and the likelihood of right heart failure. If there is clinical or laboratory evidence of left ventricular or left atrial enlargement, the probabilities are that the shunt is still predominantly left to right.

*Lung biopsies* will be of value when more experience in their interpretation is obtained. The presence of marked intimal change and complete occlusion of some arteries with widely patent vessels distally suggests irreversible damage. The presence of thick-walled small-lumened vessels with markedly hypertrophied media but little intimal change indicates that the pulmonary vascular disease is probably reversible and correction of the defect can be tolerated.

It should be stressed that therapy for the patient with a large ventricular defect and moderate to severe pulmonary vascular disease cannot be considered comparable to closure of a large patent ductus. In the former, it is necessary to approach the defect through the right ventricle. A significant portion of right ventricular wall is injured by ventriculotomy, and the efficiency of the right ventricle is temporarily but significantly decreased. Surgery should be advised *before* pulmonary vascular resistance has become close to systemic resistance.

**Corrected Transposition of the Great Vessels with a Ventricular Septal Defect.** In this malformation, the great vessels are transposed, the aorta arising in front and to the left of the

pulmonary artery. In addition, the left and right ventricles and the mitral and tricuspid valves are transposed. The left atrium communicates with a ventricle lying to the left, which has the anatomic characteristics of right ventricle and *tricuspid* valve, and communicates in turn with the transposed aorta. The right atrium communicates with a ventricle lying to the right, which has an anatomic *mitral* valve and the characteristics of left ventricle, and communicates with the pulmonary artery lying posterior to the aorta. In contrast to the usual form of ventricular defect, in this malformation, the defect opens into the right-sided (or pulmonary) ventricle immediately under the pulmonary valve in the membranous septum and into the left-sided (or systemic) ventricle behind the septal leaflet of the AV valve. Surgical exploration of the right-sided ventricle is made difficult by the anomalous position of the left anterior descending coronary artery which pursues a course directly through the mid-portion of the ventricular outflow tract. An anomaly which is frequently associated with corrected transposition and ventricular septal defect is Ebstein's malformation of the left-sided AV valve.

On *fluoroscopy*, the correct diagnosis may be suspected if particular attention is directed to the base of the heart. The left-sided aorta usually alters the left upper configuration of the heart, giving it a straight appearance which extends above the origin of both pulmonary arteries. Electrocardiographic changes relate primarily to the stress placed on one or the other ventricle by the associated ventricular defect. However, varying degrees of AV block including a complete disassociation are common, and their presence should suggest the diagnosis.

Diagnosis of this malformation depends upon the proper evaluation of the origin of the great vessels. An angiocardigram taken in the anteroposterior and the left lateral position will demonstrate that the origin of the aorta is anterior and to the left of the pulmonary artery. The right-sided ventricle presents a smooth tract along the inferior margin of the heart toward the apex. The left-sided ventricle is not smooth-walled as in the normal individual. The atria are normally positioned. During cardiac catheterization, the course of the catheter is more toward the

vere pulmonary stenosis, the main pulmonary artery segment is so small that early complete correction of the defect places an excessive strain on the right side of the heart. On the other hand, creation of a shunt is followed by enlargement of the pulmonary artery, and thus total correction becomes practical at a later date. When complete pulmonary atresia is present, a shunt procedure is the ideal approach. This should be deferred until the child is 3 or 4 years old unless the child's condition is critical. In most instances, a small but patent pulmonary artery to the left or right lung will be found although the main pulmonary artery may be atretic.

Tetralogy of Fallot associated with minimal stenosis and a large ventricular defect may be totally corrected using extracorporeal circulation. Since the lungs are protected from progressive pulmonary vascular disease by the infundibular or pulmonary stenosis, surgery can be delayed until the child has reached an adequate size and the risk of correction has been reduced to a minimum. For the small defect with marked pulmonary stenosis and minimal or extreme overriding of the aorta, the only surgical approach is complete correction because a shunt procedure too frequently produces cardiac decompensation.

**Single Ventricle with Pulmonary Stenosis and Minimal or Moderate Pulmonary Vascular Disease.** The mitral and tricuspid valves in this malformation open into the common chamber representing both the right and left ventricles. The conus area of the right ventricle forms a rudimentary outlet chamber which communicates with the main ventricular chamber through a defect. One great vessel arises from the main ventricle, the other from the rudimentary outlet chamber. Usually the aorta arises from the anteriorly placed rudimentary outlet chamber, and the pulmonary artery, from the main body of the ventricle in a transposed position. The presence or absence of a transposition of the great vessels, however, has little to do with the clinical course, which is entirely dependent upon the difference in systemic and pulmonary vascular resistances. If pulmonary resistance is low and pulmonary blood flow is high, cyanosis is absent. Despite the fact that there is complete mixing of blood in the common ventricle, the volume of saturated blood returning to the heart is suf-

ficient to raise the saturation of mixed blood above the level where cyanosis is visible.

Differential diagnosis is best made with the laboratory techniques. When the great vessels are transposed, there is a concavity in the region of the main pulmonary artery segment seen both in the PA view and RAO position; yet the lung fields appear excessively vascular. A bulge of the upper left salient of the heart, suggestive of a rudimentary outlet chamber, may be seen. It is usually difficult to be sure which chamber of the heart is enlarged. In one view, the right ventricle may appear enlarged, whereas in another, it is the left ventricle that is enlarged. As a rule, the apex is displaced inferiorly and laterally. The heart presses up against the sternum in the RAO position, but in the LAO position it cuts in anteriorly over the diaphragm, suggesting an absence of the inflow tract of the right ventricle. The ECG of many patients with a single ventricle is extremely bizarre. Not uncommonly an S wave is present in all the standard leads and in chest leads  $V_1$  to  $V_6$ . Occasionally, the chest leads pattern may be an R wave throughout. The pattern may be one of pure right or pure left ventricular hypertrophy. In this instance, the findings on fluoroscopy should be taken into account, for it is not uncommon that the chamber which appears enlarged on fluoroscopy will not be the chamber which appeared hypertrophied in the ECG.

Angiocardiographic studies may suggest the diagnosis of a single ventricle, particularly if the great vessels are transposed. Filling of the area usually occupied by the left and right ventricle will occur promptly, and in the conus position of the right ventricle, a separately delineated area may be seen, representing the rudimentary outlet chamber. Transposed great vessels in a noncyanotic patient strongly suggest a *single ventricle*. Cardiac catheterization demonstrates a distinct rise in oxygen content on passing through the tricuspid valve. The magnitude of rise demands upon the exact anatomy present, for in certain instances, there may be streaming of blood so that blood entering the tricuspid valve remains essentially venous until it reaches the outflow tract. A systemic pressure is present within the ventricle. The vessel arising from the main ventricle is usually catheterized without difficulty. Catheterization of the rudimentary out-

Under the fluoroscope, the heart has an accentuated boat shape with a marked concavity of the main pulmonary artery segment and an upturned, blunt apex. The right and left pulmonary arteries appear small, and the peripheral lung fields are clear. When there is severe stenosis associated with an increase in collateral circulation, the markings in both hilar regions may be increased, but the normal vascular pattern is lacking. Angiocardiography fails to demonstrate a main pulmonary artery but may demonstrate filling of the right and left pulmonary arteries from branches arising from the heavily opacified aorta. Cardiac catheterization reveals a severe degree of arterial unsaturation. The pulmonary artery is only rarely entered because of the severity of the stenosis.

**Tetralogy of Fallot, Large Defect with Minimal Pulmonary Stenosis.** Because the stenosis is minimal in this condition, the shunt is left to right rather than right to left. Serial catheterization studies have demonstrated that the stenosis is usually at the level of the crista supraventricularis and may not be significant in early childhood. A significant pressure drop appears as cardiac output increases with growth and a hypertrophy of the crista develops. The right ventricle is somewhat enlarged because of the increased work load brought about by the pulmonary stenosis. The left ventricle is enlarged because of the increased volume of blood returning from the lungs. Clinically, it is difficult to differentiate this condition from a large ventricular defect associated with minimal pulmonary vascular disease. A pulmonary 2d sound that is frequently split but not accentuated suggests infundibular stenosis rather than pulmonary vascular disease. Diastole is usually clear, except for a mid-diastolic rumble at the apex. The most useful differential diagnostic tool is cardiac catheterization, provided that the pulmonary artery is entered and the drop in pressure from the main right ventricle to the infundibular area, and through the valve to the pulmonary artery, is demonstrated. Pulmonary artery pressure is usually somewhat elevated, but right ventricular pressure is approximately the same as the systemic.

**Tetralogy of Fallot, Small Defect with Severe Pulmonary Stenosis and No Occluding.** The clinical, fluoroscopic, and catheterization findings all are suggestive of isolated valvular

pulmonary stenosis with a patent foramen ovale because the resistance to right ventricular outflow is extreme. Angiocardiography offers the best differential diagnosis for a right-to-left shunt occurring at the ventricular level. There is early filling of the aorta and a delayed passage of contrast medium through the lungs.

**Tetralogy of Fallot, Small Defect with Severe Stenosis and Marked Occluding of the Aorta.** In this syndrome, the major work load is placed not on the right ventricle, but upon the left. The right ventricle must meet systemic resistance and, therefore, is moderately hypertrophied. The left ventricle, however, cannot empty efficiently through the tiny ventricular defect. If there is a significant quantity of blood returning to the left side of the heart (as after a Blalock-Taussig or Potts anastomosis), left ventricular enlargement develops, and death from heart failure may occur. The differential diagnosis is extremely difficult. Cardiac catheterization reveals a systemic pressure within the right ventricle and a markedly lowered arterial oxygen saturation. The aorta is usually catheterized with ease. A left-to-right shunt at the ventricular level may be demonstrated. Angiocardiogram in the LAO projection will reveal early filling of the aorta with delayed filling of the pulmonary vascular tree. Late in the series, delayed left ventricular emptying may be demonstrated by retention of the opaque material in the left ventricle.

**THERAPY.** The therapeutic approach to all these forms of a tetralogy of Fallot is not uniform and depends upon the exact combination of defects. The most common form can be improved by creation of a Blalock-Taussig subclavian-pulmonary artery anastomosis or by a Potts aortic-pulmonary anastomosis. In more recent years, the defect has been completely repaired by closure of the defect and resection of the infundibular or valvular stenosis while using an extracorporeal circulation. When a patient with a tetralogy of Fallot is not severely incapacitated, corrective surgery should be withheld until the child is 4 years or older. On the other hand, infants suffering from attacks of paroxysmal dyspnea should have an anastomosis. This is a safer procedure in infancy and permits growth and development to the point where complete correction is possible. It is also probable that, in cases of se-

that of *left axis deviation* and *left ventricular hypertrophy*. Cardiac catheterization is of little aid, for in many instances the only chamber that can be catheterized is the right atrium. The catheter may slip through the atrial defect into the left atrium and ventricle, but it is rare to catheterize either great vessel. The findings are a rise in oxygen content at the ventricular level, with a saturation that is identical to that determined from the brachial artery. Ventricular pressure is systemic. Arterial unsaturation is present. Angiocardiography in the LAO view may be of assistance in demonstrating prompt filling of the left atrium from the right and a large and thick-walled left ventricle, with filling of the pulmonary artery and aorta from the common left ventricle. In the LAO position, that portion of the heart lying anteriorly and immediately over the diaphragm, which is usually occupied by the inflow tract of the right ventricle, does not fill with contrast medium.

**THERAPY.** A corrective therapeutic procedure for tricuspid atresia has not been developed. Consequently, the approach is palliative and consists of an anastomosis between the pulmonary artery and a systemic artery. The mortality rate during and after surgery is significantly higher than for tetralogy of Fallot. If there is evidence of obstruction between the atria at the time the anastomosis is created, the atrial defect should be enlarged. Surgery for this malformation is best carried out after the age of 2 since operation before then is attended by a greater mortality rate. However, if the patient has episodes of paroxysmal dyspnea, surgery should not be withheld.

**Tricuspid Atresia with Transposition of the Great Vessels.** This rare malformation places a severe load upon the pulmonary vascular bed, and if the patient survives the first year, the degree of pulmonary vascular disease is usually marked. A high pulmonary resistance must be maintained in order to balance, not only the normally elevated systemic resistance, but also the additional resistance to aortic flow created by the small ventricular defect and rudimentary right ventricle from which the aorta arises. In early infancy, signs and symptoms are those of a single ventricle with a high pulmonary blood flow. However, the rapid progression of the pulmonary vascular

disease decreases pulmonary blood flow, so that the signs and symptoms become those of a single ventricle with pulmonary stenosis or marked pulmonary vascular disease.

Differential diagnosis depends upon the laboratory studies. Fluoroscopy reveals increased vascular markings without fullness of the main pulmonary artery segment. The heart is usually enlarged, and the enlargement involves the right atrium, the left ventricle, and during early infancy, the left atrium. The contour of the heart may suggest a tricuspid atresia. The ECG reveals left ventricular hypertrophy. Cardiac catheterization is of little aid. Angiocardiography demonstrates the presence of tricuspid atresia and the transposed position of the great vessels.

**THERAPY.** Theoretically, the therapeutic approach should aim to relieve the resistance to aortic outflow and increase pulmonary artery resistance. Thus, to widen the ventricular septal defect and to create pulmonary stenosis would appear to be the procedure of choice. Correction of the transposition is of doubtful value since the coronary arteries would continue to arise from the obstructed vessel.

**Transposition of the Great Vessels with Patent Ductus Arteriosus or Ventricular Septal Defect.** Transposition of the great vessels has been included in group I because there is a definite relationship between alterations in the pulmonary vascular bed, size of defect, presence or absence of pulmonary stenosis, and clinical course, despite the separation of the two circulations into two independent units. A large ventricular defect or large patent ductus combined with a transposition leads to the rapid development of pulmonary vascular disease. The speed of development is enhanced by the polycythemia and perhaps by pulmonary vascular spasm induced by anoxemia.

In this malformation, the great vessels are transposed, the aorta arising from the right ventricle and the pulmonary artery from the left. Since venous return to the heart is normal, two potentially completely independent circulations exist. Venous blood returning from the body is directed through the aorta back to the body, and oxygenated blood returning from the lungs is redirected to the lungs. In the absence of any communication between the two circulations, this malformation would be incompatible with life. However, if one or

let chamber and remaining great vessel is rarely accomplished

**THERAPY.** At the present time, corrective surgery is not available. The only procedure that offers improvement is the production of pulmonary stenosis by banding the pulmonary artery to reduce its lumen size by approximately 75 per cent before pulmonary vascular disease has developed to the irreversible stage. It is best accomplished when the pulmonary blood flow is high, for determinations of pressure proximal and distal to the area of stenosis indicate whether sufficient stenosis has been created. The distal systolic pulmonary artery pressure should be lowered to 30 to 40 mm Hg. When flows are equal preoperatively, a pressure drop in the distal pulmonary artery indicates excessive stenosis; consequently, the pulmonary artery must be narrowed to a degree just a fraction less than that which will produce a pressure drop.

#### *Single Ventricle with Pulmonary Stenosis.*

In this malformation, the pulmonary stenosis is usually due to a pulmonary valve ring which is narrowed, sclerosed, and surrounded by thickened, fibrous endocardium. Signs and symptoms vary according to the degree of pulmonary stenosis. The great vessels are usually transposed. The importance of differentiating the single ventricle with pulmonary stenosis from the tetralogy of Fallot is that complete correction of the latter is practical, whereas it is not with a single ventricle. Differential diagnosis is also important because surgery of the single ventricle with pulmonary stenosis is attended by a higher mortality rate (25 per cent) than is the same palliative therapy for tetralogy of Fallot. The correct differential diagnosis is dependent upon a high level of suspicion, with attention paid to the slightest variation from the typical tetralogy of Fallot. Under the fluoroscope, the heart frequently has the contour of a tricuspid atresia. In the PA projection, the heart appears fat, and the apex extends below the diaphragm, failing to clear even on deep inspiration. In the LAO position it may cut in sharply over the diaphragm anteriorly. When the great vessels are transposed, the area usually occupied by the main pulmonary artery is occupied by the aorta; consequently, there is no concavity. The ECG usually differs from that found in tetralogy of Fallot in that it does not have a pure

pattern of right ventricular hypertrophy. Cardiac catheterization, unless both great vessels are catheterized and their origin is determined, is of little differential diagnostic aid. Angiocardiography is of help since both right and left ventricular areas are filled simultaneously, and the exact origin of the great vessels may be clarified.

**THERAPY.** Therapy is, of necessity, palliative since total correction of the defect is not yet possible. An anastomosis between a systemic artery and the pulmonary artery should be created. It is important that the shunt not be too large because, in this malformation, there is a high instance of congestive failure post-operatively.

**Tricuspid Atresia.** In this malformation, the tricuspid valve is atretic and is represented by a small dimple in the wall of the right atrium. There is no continuity of right atrium and right ventricle. The inflow tract of the right ventricle does not develop. Blood returning to the right side of the heart must pass through an atrial defect into the left atrium and left ventricle. From the left ventricle, blood may pass out of the aorta or through a ventricular defect into a rudimentary right ventricle, which communicates with the pulmonary artery. In most instances, the ventricular defect is relatively small and the rudimentary right ventricle is long and narrow, offering a significant resistance to pulmonary blood flow. Signs and symptoms are comparable to a tetralogy of Fallot and depend upon the degree of pulmonary obstruction. In addition, however, a small atrial defect may hinder the free flow of blood from right atrium to left atrium, causing an increased systemic venous pressure.

Fluoroscopic examination reveals a boot-shaped heart, which appears much thicker than is usual with the tetralogy of Fallot. There is a rounding and fullness of the left upper salient of the heart both in the PA projection and in the RAO view, which represents rudimentary right ventricle. The apex does not clear the diaphragm, and in the LAO view, there is a posterior rounding suggestive of left ventricular enlargement. The right atrium, usually normal in size in the tetralogy, not infrequently is enlarged. The left atrium is normal. The ECG presents the best differential diagnostic information. The pattern is

ventricular defect, the functional size of the latter is made larger, thus permitting a far larger<sup>1</sup> bidirectional shunt. Arterial oxygen saturation is higher and cardiac failure less common, so that this diagnosis should be suspected in any patient with a transposition living past the tenth year. The cause of death is usually related to severe pulmonary vascular disease and anoxia.

The differential diagnostic points, aside from the age of the patient, are chiefly associated with laboratory studies. X-ray and fluoroscopy reveal a fullness of the main pulmonary artery segment as visualized in the PA view, which is not often present in other forms of transposition of the great vessels. The hilar markings are increased. On angiocardiology, there is simultaneous filling of both the anteriorly placed aorta and the posteriorly placed pulmonary artery. The volume of contrast medium is greater in the aorta. During cardiac catheterization, it is usually possible to enter both the pulmonary artery and aorta and to demonstrate an increase in oxygen content in the pulmonary artery over that obtained high in the outflow tract of the right ventricle. Right ventricular and left ventricular pressures are equal. Determination of pulmonary vascular resistance indicates the presence of marked pulmonary vascular disease.

*Transposition of the Great Vessels with Large Ventricular Defect and Origin of Both Vessels from the Right Ventricle.* This malformation is a variant of the Taussig-Bing syndrome. The principal differential diagnostic finding is that obtained through angiocardiology, that there is simultaneous opacification of an anteriorly placed aorta and a posteriorly placed pulmonary artery. When visualized in the LAO projection, contrast medium returning to the left side of the heart from the lungs must pass anteriorly through a ventricular defect in order to reach the great vessels.

*Transposition of the Great Vessels with Ventricular Septal Defect and Pulmonary Stenosis.* The presence of pulmonary stenosis effectively reduces pulmonary blood flow, which decreases the likelihood of congestive failure and causes a left-to-right shunt at the ventricular level. The degree of cyanosis depends upon the severity of the pulmonary stenosis and the magnitude of the bronchial

arterial circulation. On physical examination, a high-pitched, long systolic murmur is usually present at the base of the heart, which suggests a pressure gradient across the pulmonary valve. There is no evidence of congestive failure. The pulmonary 2d sound is usually pure but *may be loud*, since it is caused by closure of the anteriorly placed aortic valve. On x-ray, the peripheral lung fields appear clear and not pulsatile, and the main pulmonary artery segment is concave. The heart is not grossly enlarged and tends to lie in a more horizontal plane rather than at a 45° angle. Evidence of left ventricular and left atrial enlargement is usually absent because of the reduction in the volume of blood returned to the left side of the heart. The ECG reveals *right axis deviation* and *pure right ventricular hypertrophy*. A misdiagnosis of tetralogy of Fallot is frequently made. Angiocardiology may establish the diagnosis if there is opacification of the pulmonary artery late in the series. However, as a rule, the only vessel to opacify is the aorta, the anterior origin of which may be suspected but not proved. In a few patients with this malformation, the aorta arises far to the left and produces a convexity in the usual position of the pulmonary artery. When this area is seen to fill with contrast solution and is defined as aorta, the diagnosis becomes clear. Cardiac catheterization is of little aid.

**THERAPY FOR TRANSPOSITION OF GREAT VESSELS** Corrective surgery for this malformation is still experimental. There are several palliative procedures which may improve exercise tolerance and prolong life expectancy. The creation of an atrial septal defect increases bidirectional shunting. The transplantation of the right pulmonary veins to the right atrium accomplishes essentially the same physiologic change. Transposition of the inferior vena cava and right pulmonary veins still further improves systemic saturation. However, none of these procedures prevents the progressive development of pulmonary vascular disease, and none establishes a circulation sufficiently adequate to give a normal life expectancy.

The ideal approach appears to be either complete transposition of the venous return to the heart<sup>2</sup> or the creation of a new atrial

<sup>2</sup> See Chap 14, Editor

let chamber and remaining great vessel is rarely accomplished

**THERAPY** At the present time, corrective surgery is not available. The only procedure that offers improvement is the production of pulmonary stenosis by banding the pulmonary artery to reduce its lumen size by approximately 75 per cent before pulmonary vascular disease has developed to the irreversible stage. It is best accomplished when the pulmonary blood flow is high, for determinations of pressure proximal and distal to the area of stenosis indicate whether sufficient stenosis has been created. The distal systolic pulmonary artery pressure should be lowered to 30 to 40 mm Hg. When flows are equal preoperatively, a pressure drop in the distal pulmonary artery indicates excessive stenosis; consequently, the pulmonary artery must be narrowed to a degree just a fraction less than that which will produce a pressure drop.

**Single Ventricle with Pulmonary Stenosis.** In this malformation, the pulmonary stenosis is usually due to a pulmonary valve ring which is narrowed, sclerosed, and surrounded by thickened, fibrous endocardium. Signs and symptoms vary according to the degree of pulmonary stenosis. The great vessels are usually transposed. The importance of differentiating the single ventricle with pulmonary stenosis from the tetralogy of Fallot is that complete correction of the latter is practical, whereas it is not with a single ventricle. Right ventricular and left ventricular pressures are equal. Determination of pulmonary vascular resistance indicates the presence of marked pulmonary vascular disease.

**Transposition of the Great Vessels with Large Ventricular Defect and Origin of Both Vessels from the Right Ventricle.** This malformation is a variant of the Taussig-Bing syndrome. The principal differential diagnostic finding is that obtained through angiocardiography, that there is simultaneous opacification of an anteriorly placed aorta and a posteriorly placed pulmonary artery. When visualized in the LAO projection, contrast medium returning to the left side of the heart from the lungs must pass anteriorly through a ventricular defect in order to reach the great vessels.

**Transposition of the Great Vessels with Ventricular Septal Defect and Pulmonary Stenosis.** The presence of pulmonary stenosis effectively reduces pulmonary blood flow, which decreases the likelihood of congestive failure and causes a left-to-right shunt at the ventricular level. The degree of cyanosis depends upon the severity of the pulmonary stenosis and the magnitude of the bronchial

arterial circulation. On physical examination, a high-pitched, long systolic murmur is usually present at the base of the heart, which suggests a pressure gradient across the pulmonary valve. There is no evidence of congestive failure. The pulmonary 2d sound is usually pure but *may be loud*, since it is caused by closure of the anteriorly placed aortic valve. On x-ray, the peripheral lung fields appear clear and not pulsatile, and the main pulmonary artery segment is concave. The heart is not grossly enlarged and tends to lie in a more horizontal plane rather than at a 45° angle. Evidence of left ventricular and left atrial enlargement is usually absent because of the reduction in the volume of blood returned to the left side of the heart. The ECG reveals *right axis deviation* and *pure right ventricular hypertrophy*. A misdiagnosis of tetralogy of Fallot is frequently made. Angiocardiography may establish the diagnosis if there is opacification of the pulmonary artery late in the series. However, as a rule, the only vessel to opacify is the aorta, the anterior origin of which may be suspected but not proved. In a few patients with this malformation, the aorta arises far to the left and produces a convexity in the usual position of the pulmonary artery. When this area is seen to fill with contrast solution and is defined as aorta, the diagnosis becomes clear. Cardiac catheterization is of little aid.

**THERAPY FOR TRANSPOSITION OF GREAT VESSELS.** Corrective surgery for this malformation is still experimental. There are several palliative procedures which may improve exercise tolerance and prolong life expectancy. The creation of an atrial septal defect increases bidirectional shunting. The transplantation of the right pulmonary veins to the right atrium accomplishes essentially the same physiologic change. Transposition of the inferior vena cava and right pulmonary veins still further improves systemic saturation. However, none of these procedures prevents the progressive development of pulmonary vascular disease, and none establishes a circulation sufficiently adequate to give a normal life expectancy.

The ideal approach appears to be either complete transposition of the venous return to the heart<sup>2</sup> or the creation of a new atrial

<sup>2</sup> See Chap. 14. Editor

more defects are present, a bidirectional shunt is established and oxygenated blood may reach the body. There is no stress on the circulation during intrauterine life. It is only following birth, when the newborn infant has become dependent upon the lungs for adequate gaseous exchange, that stress appears. Thus, the heart is of normal size at birth, but enlarges rapidly during the early months of life. Cyanosis is severe, and cardiac decompensation usually appears during the first year of life.

The incidence of failure appears to bear an inverse relationship to the size of the defect for the following reasons: patients with cyanotic heart disease develop an increased bronchial flow with an increase in size of the anastomotic channels between the pulmonary arterial bed and the bronchial vessels. Thus, in transposition of the great vessels, blood is continually drained from the aorta, entering the lungs through bronchial vessels and eventually returning to the left atrium and not the systemic circulation. If the defect connecting the two circulations is small, the volume of blood recirculating through the lungs steadily increases until failure of the left side of the heart occurs. The reason for failure of the right side of the heart is less clear but may be related to myocardial hypoxia and the increased work load placed on the right side by having to pump a highly viscous form of blood.

*Transposition of the Great Vessels with Small Patent Ductus Arteriosus and Patent Foramen Ovale.* Cyanosis is early and intense. Cardiac failure generally appears within the first few weeks of life, and the life expectancy is under 1 year. Differential diagnosis is usually not difficult, except during the first week of life. The presence of intense cyanosis associated with evidence of biventricular enlargement and cardiac failure is strong presumptive evidence. Differential cyanosis may be present if the direction of shunt through the patent ductus arteriosus is from pulmonary artery to aorta, for the oxygen content of blood in the descending aorta is higher than in the ascending aorta.

On physical examination, the baby appears acutely ill, with rapid respirations and intense cyanosis. Peripheral pulses may be normal. The heart is enlarged, the apex is frequently in the 5th left interspace in the anterior axillary line. Murmurs are usually absent. The 2d heart

sound at the base is accentuated and usually split. Rales are frequently heard over the lungs, and there is evidence of increased systemic venous pressure, with enlargement of the liver and a thick skin. On x-ray and fluoroscopy, the earliest differential diagnostic point is the axis of the heart. Instead of lying transversely, the long axis of the heart is at a 45° angle, suggesting equal enlargement of both the left and right ventricle. The main pulmonary artery segment is concave. The peripheral lung fields appear vascular and pulsatile. The ECG reveals a normal neonatal pattern, except for increased amplitude in the chest leads. The angiocardigram reveals early filling of the aorta which, in the oblique views, lies anteriorly. It is unusual to see contrast solution in the lungs. Cardiac catheterization is of little diagnostic aid.

*Transposition of the Great Vessels with Large Ventricular Septal Defect and Moderate to Severe Pulmonary Vascular Disease.* This combination is more compatible with life than that just discussed. Failure appears late, if at all, and the cause of death is usually anoxia rather than cardiac decompensation. Cyanosis is usually intense. The physical findings are similar to those of a transposition and a small patent ductus, except for the absence of cardiac failure and the presence of a murmur at the base of the heart. The most likely associated anomaly is a large ventricular septal defect. X-ray reveals a heart with its long axis at a 45° angle, a concave main pulmonary artery segment, vascular lung fields, and enlargement of all chambers. Angiocardigraphy reveals the anterior origin of the aorta and may suggest a right-to-left shunt at the ventricular level, with some opacification of the posteriorly placed pulmonary artery. Cardiac catheterization reveals the presence of a left-to-right shunt at the ventricular level, a common systolic pressure within both ventricles, and when the aorta is entered, confirmation of the anterior origin of the aorta.

*Transposition of the Great Vessels with Large Ventricular Septal Defect, Overriding Pulmonary Artery, and Moderate to Severe Pulmonary Vascular Disease (Taussig-Bing Syndrome).* In this malformation, the pulmonary artery is not completely transposed but overrides a ventricular defect. Because of the origin of the pulmonary artery just above the

ventricular defect, the functional size of the latter is made larger, thus permitting a far larger bidirectional shunt. Arterial oxygen saturation is higher and cardiac failure less common, so that this diagnosis should be suspected in any patient with a transposition living past the tenth year. The cause of death is usually related to severe pulmonary vascular disease and anoxia.

The differential diagnostic points, aside from the age of the patient, are chiefly associated with laboratory studies. X-ray and fluoroscopy reveal a fullness of the main pulmonary artery segment as visualized in the PA view, which is not often present in other forms of transposition of the great vessels. The hilar markings are increased. On angiocardiology, there is simultaneous filling of both the anteriorly placed aorta and the posteriorly placed pulmonary artery. The volume of contrast medium is greater in the aorta. During cardiac catheterization, it is usually possible to enter both the pulmonary artery and aorta and to demonstrate an increase in oxygen content in the pulmonary artery over that obtained high in the outflow tract of the right ventricle. Right ventricular and left ventricular pressures are equal. Determination of pulmonary vascular resistance indicates the presence of marked pulmonary vascular disease.

*Transposition of the Great Vessels with Large Ventricular Defect and Origin of Both Vessels from the Right Ventricle.* This malformation is a variant of the Taussig-Bing syndrome. The principal differential diagnostic finding is that obtained through angiocardiology, that there is simultaneous opacification of an anteriorly placed aorta and a posteriorly placed pulmonary artery. When visualized in the LAO projection, contrast medium returning to the left side of the heart from the lungs must pass anteriorly through a ventricular defect in order to reach the great vessels.

*Transposition of the Great Vessels with Ventricular Septal Defect and Pulmonary Stenosis.* The presence of pulmonary stenosis effectively reduces pulmonary blood flow, which decreases the likelihood of congestive failure and causes a left-to-right shunt at the ventricular level. The degree of cyanosis depends upon the severity of the pulmonary stenosis and the magnitude of the bronchial

arterial circulation. On physical examination, a high-pitched, long systolic murmur is usually present at the base of the heart, which suggests a pressure gradient across the pulmonary valve. There is no evidence of congestive failure. The pulmonary 2d sound is usually pure but may be loud, since it is caused by closure of the anteriorly placed aortic valve. On x-ray, the peripheral lung fields appear clear and not pulsatile, and the main pulmonary artery segment is concave. The heart is not grossly enlarged and tends to lie in a more horizontal plane rather than at a 45° angle. Evidence of left ventricular and left atrial enlargement is usually absent because of the reduction in the volume of blood returned to the left side of the heart. The ECG reveals right axis deviation and pure right ventricular hypertrophy. A misdiagnosis of tetralogy of Fallot is frequently made. Angiocardiology may establish the diagnosis if there is opacification of the pulmonary artery late in the series. However, as a rule, the only vessel to opacify is the aorta, the anterior origin of which may be suspected but not proved. In a few patients with this malformation, the aorta arises far to the left and produces a convexity in the usual position of the pulmonary artery. When this area is seen to fill with contrast solution and is defined as aorta, the diagnosis becomes clear. Cardiac catheterization is of little aid.

**THERAPY FOR TRANSPOSITION OF GREAT VESSELS** Corrective surgery for this malformation is still experimental. There are several palliative procedures which may improve exercise tolerance and prolong life expectancy. The creation of an atrial septal defect increases bidirectional shunting. The transplantation of the right pulmonary veins to the right atrium accomplishes essentially the same physiologic change. Transposition of the inferior vena cava and right pulmonary veins still further improves systemic saturation. However, none of these procedures prevents the progressive development of pulmonary vascular disease, and none establishes a circulation sufficiently adequate to give a normal life expectancy.

The ideal approach appears to be either complete transposition of the venous return to the heart<sup>2</sup> or the creation of a new atrial

<sup>2</sup> See Chap 14. *Editor.*

septum, which directs caval return through the mitral valve and pulmonary venous return through the tricuspid valve. This procedure appears technically feasible when using extracorporeal circulation. However, it must be done at an early age, before pulmonary vascular disease has developed to an excessive degree, which adds to the procedure the major complication of infancy and small patient size.

**Defects between the Ventricles or Great Vessels with Obstruction of the Pulmonary Venous Return.** In contrast to the malformations which have been discussed so far, damage occurs to the lungs in utero when obstruction of the pulmonary venous return is present prior to birth. Such obstruction may consist of anomalies of the pulmonary veins, mitral atresia associated with a closed or small foramen ovale and a *cor triaunculare*. Damage in utero occurs because the major resistance to pulmonary blood is venous and not arterial, this leads to dilatation and hypertrophy of the capillaries, thickening of the alveolar wall, and the deposition of hyaline material and cellular infiltrate between the capillary and alveolar walls. Thus, gaseous exchange after birth is hindered by a diffusion problem. In addition, the lowered pulmonary arteriolar resistance transmits a greater load from the pulmonary arterial bed to the obstructed venous return, and pulmonary vascular disease develops rapidly. Consequently, when a defect between the great vessels or ventricles is associated with pulmonary venous obstruction, the symptomatology, course, and prognosis for survival are much worse. Pulmonary vascular disease is intense, and as a rule the patient does not pass through the phase of high output cardiac failure, but passes directly to the phase of right-to-left shunt with severe hypoxia associated with attacks of paroxysmal dyspnea and early death. The increase in magnitude of pulmonary vascular disease is attested to by the lumen-wall ratio.

**Aortic and Mitral Atresia with Patent Ductus Arteriosus and Small Patent Foramen Ovale.** In this malformation, since the mitral valve is atretic, the left ventricle forms a small blind sac or communicates with the right ventricle through a small ventricular defect. The total cardiac output passes through the pulmonary artery, with some blood reaching

the lungs but the major portion passing through a large patent ductus into the aorta, because of the high pulmonary vascular resistance. The aorta, proximal to the origin of the ductus, becomes progressively smaller, so that the ascending aorta is tiny and ends in an atretic aortic valve and the two coronary arteries. The left atrium and pulmonary veins are abnormally small. Since the valve of the foramen ovale lies on the left atrial side, any increase in pressure in the left atrium without other avenues of egress tends to close the valve, making it more difficult for blood returning from the lungs to reach the systemic circulation. This pulmonary venous obstruction leads to the production of early alveolar wall thickening and capillary damage. Resistance to pulmonary blood flow is high at the time of birth and remains high. The heart tends to be abnormally large at the time of birth, for reasons probably associated with inadequate coronary blood flow, and enlarges very rapidly in the newborn period. Hypoxia is extreme, and death generally occurs during the first week of life, not only because of the high pulmonary resistance, but also because of the diffusion difficulty resulting from the thickened capillary and alveolar wall.

**Aortic atresia** should be suspected in the child who is intensely cyanotic in the first hours of life. The peripheral pulses are weak, and the heart is enlarged. Murmurs are usually absent. The 2d heart sound is pure. There is evidence of systemic venous congestion, but the lungs are clear. The ECG reveals right ventricular hypertrophy. On fluoroscopy, the heart is large because of enlargement of the right ventricle, right atrium, and a convex main pulmonary artery segment. The peripheral lung fields are clear.

It is essential to distinguish this malformation from isolated valvular pulmonary stenosis, since pulmonary stenosis can be cured surgically and aortic atresia cannot. The findings may be similar. In this condition, however, a systolic murmur over the base of the heart is seldom heard, whereas with extreme valvular pulmonary stenosis and a patent foramen ovale, a murmur is usually present. In aortic atresia, the right ventricle, pulmonary artery, and descending aorta are rapidly visualized with contrast medium, but the ascending aorta

and the right and left pulmonary arteries are small.

At the present time, there is no therapy.

**Mitral Atresia with Ventricular Septal Defect and Patent Foramen Ovale.** In contrast to the malformation just discussed, some of the blood reaching the aorta passes through a ventricular septal defect and into the ascending aorta. The major portion, however, reaches the aorta through a ductus arteriosus. The clinical manifestations, course, and prognosis are similar to those of aortic atresia plus mitral atresia.

**Congenital Mitral Stenosis with a Patent Ductus Arteriosus.** In this malformation, the primary lesion is severe mitral stenosis caused by an abnormally small valve ring and a thickened, abnormally formed mitral valve with shortened chordae tendineae, and frequently with adhesions of part of the valve leaflet to the wall of the ventricle. Pulmonary venous and capillary changes occur prior to birth because of the mitral obstruction, and a markedly elevated pulmonary resistance remains after birth. The clinical findings are those of a large patent ductus arteriosus associated with severe pulmonary vascular disease. Cyanosis is usually present early, and differential cyanosis between the upper and lower extremities may be noted.

The correct diagnosis of this malformation depends upon recognition of the mitral stenosis, which is suggested by the presence of a long diastolic rumble at the apex. Frequently, there is a systolic murmur indicative of some degree of mitral insufficiency. Marked enlargement of the left atrium may be noted on fluoroscopy. The ECG shows a notched P wave in the limb leads and a large P wave with a short P-R interval over the left precordial leads, indicative of left atrial hypertrophy. Angiocardiography confirms the presence of a large left atrium and usually demonstrates the presence of a patent ductus arteriosus, a high pulmonary artery pressure, and marked elevation of the pulmonary wedge pressure.

**THERAPY.** Closure of the ductus should be of benefit unless the shunt is predominantly right to left. If possible, dilatation of the mitral valve should be attempted, but since the usual form of congenital mitral stenosis consists of a very small mitral ring, correction of the steno-

sis is extremely difficult. In the presence of a predominant right-to-left shunt, a two-staged surgical approach should be tried. The mitral stenosis should be corrected. Sufficient time should then be allowed for a decrease in pulmonary resistance, and then an attempt should be made to close the patent ductus arteriosus.

**Congenital Mitral Stenosis with a Ventricular Septal Defect.** In this malformation, the predominant lesion again is mitral stenosis. The findings are those of a ventricular septal defect with moderate to marked pulmonary vascular disease and with mitral stenosis. When the shunt is predominantly left to right, the surgical approach is closure of the defect and resection of the stenosis under direct vision, using extracorporeal circulation. If the shunt is predominantly right to left, the mitral stenosis should be relieved first, thus permitting a drop in pulmonary resistance, at a later date, attempts can be made to close the defect.

## GROUP II: DEFECTS BETWEEN THE ATRIA

The direction and volume of shunt depend upon the relative filling pressure of the right and left ventricles. Normally, the tricuspid orifice is larger than the mitral and the inflow tract of the right ventricle is wider than that of the left. After birth, the difference between pulmonary and systemic vascular resistance leads to progressive thickening of the left ventricle and thinning of the right. Because of these differences, it takes less pressure to fill the right ventricle, and the normal left atrial pressure is significantly greater than the right. When the two atria communicate through a large defect, an essentially uniform pressure exists, which is lower than the normal left atrial pressure and higher than the right. A left-to-right shunt develops, the stroke volume of the right ventricle is greater than the left, and the size of the right ventricular chamber increases. Increased chamber size leads to decreased filling pressure, an increased shunt, and further dilatation of the right ventricle. It is only when the right ventricle fails to empty that filling pressure rises; then the shunt is decreased and, perhaps, reversed.

Since the right and left ventricles are essentially the same size at birth, the left-to-right shunt is small. Pulmonary resistance falls, and the fetal pulmonary vascular pattern is not

septum, which directs caval return through the mitral valve and pulmonary venous return through the tricuspid valve. This procedure appears technically feasible when using extracorporeal circulation. However, it must be done at an early age, before pulmonary vascular disease has developed to an excessive degree, which adds to the procedure the major complication of infancy and small patient size.

**Defects between the Ventricles or Great Vessels with Obstruction of the Pulmonary Venous Return.** In contrast to the malformations which have been discussed so far, damage occurs to the lungs in utero when obstruction of the pulmonary venous return is present prior to birth. Such obstruction may consist of anomalies of the pulmonary veins, mitral atresia associated with a closed or small foramen ovale and a *cor triauriculare*. Damage in utero occurs because the major resistance to pulmonary blood is venous and not arterial, thus leads to dilatation and hypertrophy of the capillaries, thickening of the alveolar wall, and the deposition of hyaline material and cellular infiltrate between the capillary and alveolar walls. Thus, gaseous exchange after birth is hindered by a diffusion problem. In addition, the lowered pulmonary arteriolar resistance transmits a greater load from the pulmonary arterial bed to the obstructed venous return, and pulmonary vascular disease develops rapidly. Consequently, when a defect between the great vessels or ventricles is associated with pulmonary venous obstruction, the symptomatology course, and prognosis for survival are much worse. Pulmonary vascular disease is intense, and as a rule the patient does not pass through the phase of high output cardiac failure, but passes directly to the phase of right-to-left shunt with severe hypoxia associated with attacks of paroxysmal dyspnea and early death. The increase in magnitude of pulmonary vascular disease is attested to by the lumen-wall ratio.

**Aortic and Mitral Atresia with Patent Ductus Arteriosus and Small Patent Foramen Ovale.** In this malformation, since the mitral valve is atretic, the left ventricle forms a small blind sac or communicates with the right ventricle through a small ventricular defect. The total cardiac output passes through the pulmonary artery, with some blood reaching

the lungs but the major portion passing through a large patent ductus into the aorta, because of the high pulmonary vascular resistance. The aorta, proximal to the origin of the ductus, becomes progressively smaller, so that the ascending aorta is tiny and ends in an atretic aortic valve and the two coronary arteries. The left atrium and pulmonary veins are abnormally small. Since the valve of the foramen ovale lies on the left atrial side, any increase in pressure in the left atrium without other avenues of egress tends to close the valve, making it more difficult for blood returning from the lungs to reach the systemic circulation. This pulmonary venous obstruction leads to the production of early alveolar wall thickening and capillary damage. Resistance to pulmonary blood flow is high at the time of birth and remains high. The heart tends to be abnormally large at the time of birth, for reasons probably associated with inadequate coronary blood flow, and enlarges very rapidly in the newborn period. Hypoxia is extreme, and death generally occurs during the first week of life, not only because of the high pulmonary resistance, but also because of the diffusion difficulty resulting from the thickened capillary and alveolar wall.

**Aortic atresia** should be suspected in the child who is intensely cyanotic in the first hours of life. The peripheral pulses are weak, and the heart is enlarged. Murmurs are usually absent. The 2d heart sound is pure. There is evidence of systemic venous congestion, but the lungs are clear. The ECG reveals right ventricular hypertrophy. On fluoroscopy, the heart is large because of enlargement of the right ventricle, right atrium, and a convex main pulmonary artery segment. The peripheral lung fields are clear.

It is essential to distinguish this malformation from isolated valvular pulmonary stenosis, since pulmonary stenosis can be cured surgically and aortic atresia cannot. The findings may be similar. In this condition, however, a systolic murmur over the base of the heart is seldom heard, whereas with extreme valvular pulmonary stenosis and a patent foramen ovale, a murmur is usually present. In aortic atresia, the right ventricle, pulmonary artery, and descending aorta are rapidly visualized with contrast medium, but the ascending aorta

to the axilla. The 2d sound at the base is split and usually somewhat accentuated. In some patients, a decrescendo murmur of pulmonic insufficiency may be heard along the left sternal border. Except when the right ventricle has failed, the lungs are clear, hepatic enlargement is not present, and there is no peripheral edema.

The peripheral pulmonary vascular markings are increased and actively pulsatile, and the primary vessels are convex, dilated, and pulsating. Evidence of right ventricular enlargement is present in the lateral displacement of the apex, and a decrease in the retrosternal space is noted in the RAO view. The dorta is small, the left ventricle and atrium are normal in size. The ECG presents the pattern of an *incomplete right bundle branch block with diastolic overload of the right ventricle*, characterized by an RSR' pattern in the right precordial leads. An angiocardiogram demonstrates a large pulmonary artery and large right ventricle and atrium, which reopacify early in the series. Flow through the lungs is rapid. If cinefluorography is used, there may be intermittent opacification of the left atrium when visualized in the LAO view. It is frequently possible to catheterize both the left atrium and left ventricle, in addition to demonstrating a left-to-right shunt at the atrial level. A pressure gradient across the pulmonary valve may be present, depending upon the degree of "relative stenosis," and may be expected to disappear following closure of the defect.

**THERAPY.** Surgical closure of the septum secundum defect has been sufficiently developed and may be warranted for any young person over the age of 10 years with evidence of right ventricular enlargement, even in the absence of symptoms, because the likelihood of irreversible pulmonary vascular disease at an older age is very great. The methods of closure are varied and too numerous to be detailed here.

**Septum Secundum Defect with Minimal Pulmonary Vascular Disease and Partial Anomaly of the Pulmonary Venous Return.** In this malformation, one or more of the pulmonary veins may enter the right atrium either directly or via the superior or inferior vena cava or the coronary sinus. As a consequence, the left-to-right shunt is larger in the newborn

period; signs, symptoms, and pulmonary vascular disease are more likely to develop at an earlier age, particularly if more than one pulmonary vein enters the atrium. The clinical findings cannot be differentiated from those of a simple secundum defect. The differential diagnosis rests upon accurate cardiac catheterization and dye-dilution studies. The differential injection of dye into the right and left pulmonary arteries separately may indicate the location of an anomalous vein.

**THERAPY.** The presence of an anomalous pulmonary vein increases the need for surgical correction. When closing an atrial septal defect, the surgeon should always inspect for an anomalous vein and, if present, should divert it into the left atrium.

**Septum Secundum Defect with Mild to Moderate Pulmonary Stenosis.** In this malformation, the direction and volume of shunt depend upon the severity of the pulmonary stenosis. When the stenosis is mild, the shunt is from left to right, and symptoms are comparable to those of a simple secundum defect. When the stenosis is moderate, the volume of shunt is decreased since right ventricular filling pressure is increased. There may be periods of right ventricular failure when increased cardiac output is necessitated by exercise or pulmonary resistance is further elevated by a concomitant pulmonary infection. Dyspnea is severe with exercise, and cyanosis may be apparent. On examination, the *systolic murmur* at the base of the heart is loud, long, and often high-pitched, without the characteristics which are usually associated with a simple septum secundum defect. The ECG may give evidence of both *systolic and diastolic overload* of the right ventricle. A pressure gradient drop across the pulmonary valve is present which, if minimal and accompanied by a large left-to-right shunt, will disappear following closure of the defect. If the pressure differential is below 50 mm Hg and the shunt is large, surgical closure reestablishes a normal pressure relationship. However, if the pressure gradient is over 50 mm Hg and the shunt is small, the stenosis is truly significant and should be corrected. Consequently, before deciding whether to perform a pulmonary valvulotomy, right ventricular and pulmonary artery pressures should be obtained at the time of surgery both before and after closure of the defect.

maintained Pulmonary pressure becomes elevated only after the total pulmonary vascular bed has been utilized, either because of the magnitude of the shunt or the reduction in lung mass caused by repeated parenchymal infection. Elevated pulmonary pressure ultimately leads to pulmonary vascular disease, which is characterized by predominant intimal proliferation in contrast to the predominant medial hypertrophy accompanying the large ventricular defect. The rapidity with which pulmonary vascular disease develops is extremely variable. Once it has started, however, it tends to progress with increasing momentum.

Since the chamber size and filling pressure of the right ventricle (rather than the resistance offered by the defect itself) control the volume of shunt, the clinical manifestations cannot be discussed in terms of a large, medium, or small defect. An exception to this is the patent foramen ovale associated with Ebstein's malformation of the tricuspid valve or with severe right ventricular outflow obstruction; then, the foramen is functionally patent only when the right atrial pressure exceeds the left. Consequently, the factors which alter the clinical syndrome presented by a patient with an atrial defect relate to the degree of pulmonary stenosis or the magnitude of pulmonary vascular disease and to the age of the patient when a high flow develops. A small shunt after birth permits normal disuse atrophy of the pulmonary vessels and a normal low pulmonary vascular resistance. A large shunt after birth utilizes the total pulmonary vascular bed and leads to the retention of the fetal pulmonary vascular bed. Therefore, the discussion of this group of malformations should be broken down according to the stage of development in which stress becomes significant and the pressure and degree of pulmonary stenosis or pulmonary vascular disease. Therefore, comprehensive grouping is not so applicable as with the malformation listed in group I.

**Septum Secundum Defect with Minimal Pulmonary Vascular Disease.** In this relatively common malformation the atrial defect involves that portion of septum which is clearly above the AV valves and usually contains the foramen ovale. It rarely causes severe symptoms in early childhood, for symptoms are

absent until the volume of shunt has achieved significant proportions. The date of onset of symptoms is extremely variable, which may be related to (1) the changes in the total available pulmonary vascular bed brought about by recurrent infections or structural pulmonary disease, (2) the structural differences in the right ventricle permitting a lower filling pressure in certain individuals, (3) the susceptibility and rapidity of response of the pulmonary vascular bed to the elevated flow. Rapidly progressive pulmonary vascular disease occurs most frequently during the late teens. It is rather common to see a patient, who is free of symptoms and has only a minimal increase in pulmonary resistance, develop in a matter of months a right-to-left shunt and such extensive irreversible pulmonary vascular damage that surgical correction is impossible.

It is usual to see left atrial enlargement, despite the large return of blood to that chamber, for the wall of the left atrium is more muscular and less distensible than that of the right. When the heart fails, the venous pressure is elevated not only in the systemic circulation, but in the pulmonary circulation as well, causing symptoms of systemic and pulmonary congestion. It is probable that both ventricles fail, though for different reasons.

Signs and symptoms are related to the volume of shunt and the efficiency of the right ventricle. Exertional dyspnea and impaired growth and development are common, because of a high incidence of pulmonary infection, pulmonary congestion, and perhaps also a reduced systemic blood flow. Right heart failure causes severe exertional dyspnea, peripheral edema, orthopnea, and pulmonary congestion. Peripheral pulses are normal. A bulge of the precordium, increased precordial activity, and an impulse close to the sternum, which is strikingly more forceful than that at the apex, suggest that the right ventricle alone is under stress. The apical thrust is displaced laterally. A systolic murmur, probably caused by relative pulmonary stenosis, is usually heard over the base of the heart. It is short, early in timing, moderately loud, and transmitted over the lungs. A mid-diastolic rumble is frequently heard just medial to the apex, in contrast to the murmur of mitral stenosis, it is better transmitted toward the sternum than outward.

may be demonstrated by catheterization. Careful pullback pressure tracings from the pulmonary artery into the right ventricle usually should isolate the area of stenosis to the valve ring. Arterial unsaturation is present.

**THERAPY.** The best approach, except in the tiny infant, appears to be direct visualization of the pulmonary valve through the open pulmonary artery during inflow occlusion, using either *hypothermia* or *extracorporeal circulation*. In adults, who have developed sufficient hypertrophy and scarring of the ventricular outflow tract to cause further obstruction, extracorporeal circulation should probably be used in order to gain sufficient time to correct the additional stenosis. The blind approach to the pulmonary valve through the right ventricle in the small infant still appears safer and adequate, since there is much less right ventricular hypertrophy and the pulmonary valve itself is thin, easily torn, and less liable to stretch. However, the efficacy of valvulotomy should be determined by preoperative and postoperative pressure tracings, and if adequate relief of stenosis has not been achieved, a second attempt should be made.

**Patent Foramen Ovale with Infundibular Pulmonary Stenosis.** In this malformation, the area of stenosis is located proximal to the pulmonary valve, in the infundibular portion of right ventricle. The signs and symptoms closely simulate those of isolated valvular pulmonary stenosis and patent foramen ovale, except for the position and spread of the *systolic murmur* which is usually *high-pitched, long, and heard best in the 3d left interspace*, not well transmitted toward the left clavicle. A split soft 2d sound may be present, and diastole is clear. On fluoroscopy, in contrast to valvular stenosis, the main pulmonary artery segment is *not* convex in the PA and RAO views, and there is no enlargement of the major branches. The angiocardigram may indicate that the stenosis lies proximal to the pulmonary valve and is separated from the pulmonary valve by an infundibular chamber. Catheterization with slow pullback maneuvers from the pulmonary artery into the right ventricle should indicate the point of stenosis. In the infundibular chamber, the systolic pressure is equal to that of the main pulmonary artery, but the diastolic pressure approaches zero.

**THERAPY.** Corrective surgery consists of excision of the stenotic area under direct vision, using inflow occlusion with either *extracorporeal circulation* or *hypothermia*. The former seems preferable because of the length of time it may take to perform an adequate resection. The area of stenosis may be approached from either the right ventricular wall or the pulmonary artery.

**Patent Foramen Ovale with Severe Pulmonary Vascular Disease.** In this condition, the primary disease process is in the pulmonary vascular bed. Sufficient elevation of pulmonary resistance occurs to produce marked right ventricular hypertrophy, an increase in filling pressure of the right ventricle,<sup>6</sup> and a right-to-left shunt through the probe-patent foramen ovale. The etiology of the disease is not understood, although there is some evidence to suggest a neurogenic origin. The early morphologic changes are primarily *medial hypertrophy* of the small pulmonary vessels and *small areas of acute pulmonary arteritis*. Thickening of the veins is also present. The terminal picture is one of severe pulmonary artery obstruction with marked intimal proliferation, destruction of the media with replacement by fibrous tissue, and suggestive evidence of *thrombus* formation. Distal to the point of obstruction, thin-walled dilated pulmonary vessels may be seen. The age of onset of symptoms is highly variable.

The symptoms suggest valvular pulmonary stenosis. *Cyanosis* and *dyspnea* are severe. Right heart failure is progressive and eventually leads to death. On physical examination, the right ventricle is found to be enlarged and evidence of failure may be present. A short basal systolic murmur may be present. The 2d sound at the base of the heart is *accentuated* and *split*. A long *decrecendo diastolic blowing murmur* along the left sternal border suggests *pulmonary insufficiency*. The ECG reveals a *systolic overload* of the right ventricle and a *tall peaked P wave* suggestive of right atrial hypertrophy. The x-ray and fluoroscopy picture frequently resembles that of isolated valvular pulmonary stenosis. In a few instances, however, there may be increased peripheral pulmonary markings, sug-

\* See note 6 Editor.

**Septum Secundum Defect with Severe Pulmonary Stenosis.** In this malformation, the severity of the pulmonary stenosis produces a decreased pulmonary blood flow, an increased filling pressure of the right ventricle\* (greater than that of the left ventricle), and a predominant right-to-left shunt through the atrial defect. Cyanosis, severe exertional dyspnea, and orthopnea† are occasionally seen. The *systolic* murmur at the base of the heart is high-pitched, long, loud, well transmitted upward, toward the left clavicle, and is accompanied by a thrill. The pulmonary 2d sound is pure and soft. Presystolic pulsations of the liver may be present. A decrescendo murmur of pulmonary insufficiency is not present nor is the mid-diastolic rumble of relative tricuspid stenosis. The right ventricle and right atrium are seen enlarged on fluoroscopy and the main pulmonary artery is full and pulsatile, but in contrast to this, the pulmonary stems are less pulsatile and the peripheral lung fields are clear and show no pulsations.

There is evidence in the ECG of both *systolic* and *diastolic* overload of the right ventricle, characterized by an RSR' pattern in the right precordial leads, associated with a tall R and a deep S over the left precordial leads. T wave changes suggestive of right strain are present. Cardiac catheterization helps to differentiate this defect from isolated valvular pulmonary stenosis with patent foramen ovale, for in the latter, there is evidence of a small left-to-right shunt. With cinefluorography, the bidirectional shunt through the atrial septum may outline the defect, and the exact site of the stenosis may be localized.

**THERAPY.** The importance of the differentiation between valvular pulmonary stenosis associated with large atrial defect and one with a patent foramen ovale is in the surgical correction. Resection of the area of stenosis when the atrial defect is large will produce a large left-to-right shunt through the defect, pulmonary vascular engorgement, a decreased

systemic flow, and early decompensation. This does not happen in a case with foramen ovale. Both the stenosis and the atrial septum should be corrected at the same time in order to avoid this sequence of events.

**Patent Foramen Ovale with Severe Pulmonary Valvular Stenosis.** The foramen ovale, normally patent at birth, remains patent anatomically (but not functionally) in 25 per cent of normal adults. Normally, left atrial pressure, which is higher than the right, keeps the valve functionally closed since the valve of the foramen ovale lies on the left atrial side. However, when right atrial pressure rises above the left, the valve opens and a right-to-left shunt develops. In this malformation, the severe obstruction to the outflow of blood from the right ventricle raises the filling pressure of the right ventricle, thus increasing right atrial pressure and producing a right-to-left shunt through the foramen ovale‡.

Signs and symptoms relate to the pulmonary stenosis which causes a decreased pulmonary blood flow, exertional dyspnea, and fatigability. The right-to-left shunt produces cyanosis. Heart failure may be present but is not associated, however, with orthopnea or evidence of pulmonary congestion. There is a variable degree of cyanosis and clubbing, a bulge of the left chest, somewhat increased precordial activity, and a forceful right ventricular impulse. The apex of the heart is displaced laterally. There is a long, loud, high-pitched *systolic* murmur, associated with a *systolic* thrill, maximal in the 2d left interspace, equally well heard in the 1st left interspace, and well transmitted upward toward the left clavicle. The pulmonary 2d sound is pure and soft, and diastole is clear. There may be evidence of right heart failure. The ECG reveals *systolic* overload of the right ventricle and right ventricular strain. On fluoroscopy, the right ventricle and atrium are enlarged. The main pulmonary arteries are full and somewhat pulsatile, the distal pulmonary arteries are small and quiet. By angiocardiology, there is a right-to-left shunt at the atrial level, an obstruction to outflow of blood from the right ventricle, and a delayed passage of contrast medium through the lungs. The area of valvular stenosis may be visualized. A marked pressure gradient across the pulmonary valve

\* Theoretically, this increase in the diastolic pressure of the right ventricle should be considered evidence of initial right ventricular failure. Editor.

† As the right-to-left shunt bypasses the lungs, these symptoms cannot be attributed to increased pulmonary flow. Rather, they can be explained as the result of left ventricular failure, possibly favored by increased inflow and lower saturation of arterial blood. Editor.

‡ See note 6. Editor.

stenosis makes differential diagnosis difficult. The rumble of mitral stenosis, however, is heard maximally at the apex and is well transmitted toward the left axilla, whereas that of functional tricuspid stenosis is heard maximally medial to the apex and transmitted better toward the sternum. Cardiac catheterization may establish the diagnosis for, if the left atrium and left ventricle are catheterized, a *diastolic pressure gradient across the mitral valve* will be observed.

**THERAPY.** This lesion is far less common than it was previously thought. The mitral stenosis must be treated at the same time that the defect is closed, or acute pulmonary edema will develop. Treatment of an acquired mitral stenosis is relatively simple, but treatment of congenital mitral stenosis may be impossible because of a tiny valve ring and totally malformed leaflets, which are frequently adherent to the endocardium. Since the exact abnormality of the mitral ring can be established only during surgery, the patient's prognosis cannot be determined preoperatively.

**Septum Secundum Defect with Transposition of the Great Vessels.** This rare form of transposition of the great vessels usually causes death in the first few months of life, this is due to severe hypoxia, complicated by congestive failure. Pulmonary resistance falls immediately after birth since there is no defect at the ventricular or great vessel level. Pulmonary blood flow increases progressively, and pulmonary congestion occurs early. Examination of the small arteries of the lungs reveals much less medial hypertrophy than is found in other forms of great vessel transposition. Murmurs are usually absent, cardiac failure appears early and is severe. Despite marked cardiomegaly, the left atrium is *not* enlarged. Determination of left atrial size, therefore, is essential to the differential diagnosis. A left-to-right shunt at the atrial level is demonstrated by catheterization. An angiocardiogram in the LAO view shows filling of the left atrium from the right atrium, without evidence of a ventricular defect or patent ductus.

**THERAPY.** This form of transposition of the great vessels is theoretically totally correctable by relocation of the atrial septum in such a manner that venous blood is directed through the mitral valve and oxygenated blood through the tricuspid valve. Such a procedure is fac-

ilitated by the absence of other intracardiac defects and the absence of severe pulmonary vascular disease.

**Septum Primum Defect with a Cleft Mitral Valve.** The position of the septum primum defect differs from the more common form of secundum defect in that the defective area lies just over the tricuspid and mitral valves and involves the septal leaflet of the two valves. The separate halves of the mitral and tricuspid septal leaflets fail to fuse completely, thus forming a *cleft leaflet*, which produces mitral or tricuspid insufficiency, or both. In addition to the increased right ventricular work load caused by the septal defect, valvular insufficiency places a burden on the ventricle involved. *Mitral insufficiency* is the most common. The volume of blood regurgitated into the atrium from the left ventricle increases pulmonary venous pressure. As a consequence, some degree of pulmonary hypertension is retained after birth and a normal development of the pulmonary vascular pattern is not followed. Thus, a factor of moderate-to-marked pulmonary hypertension complicates the physiologic alterations produced by a simple atrial defect, and frequently produces early right ventricular failure, a right-to-left shunt, and cyanosis.

Correct diagnosis is sometimes extremely difficult. The presence of a *large left ventricle* differentiates this malformation from a simple secundum defect, but does not differentiate it from either an atrioventricularis communis or a large ventricular defect. A normal-sized left atrium differentiates this malformation from a large ventricular defect, but not from an atrioventricularis communis. The early development of cardiac failure in a child with an atrial defect should make one suspicious of a primum defect associated with a cleft mitral valve. The murmurs usually associated with an atrial defect are heard, and in addition, there is a systolic murmur at the apex which radiates laterally and suggests mitral insufficiency. Under the fluoroscope, both ventricles and the right atrium are enlarged. The left atrium is normal. The ECG shows evidence of *biventricular enlargement* and *hypertrophy* without evidence of left atrial enlargement. Cardiac catheterization demonstrates the presence of a large left-to-right shunt at the atrial level. Blood samples from the right

festive of vascular disease rather than pulmonary stenosis.

The chief differential diagnostic tool is cardiac catheterization. The absence of a pressure gradient across the pulmonary valve is demonstrated, if the pulmonary artery is catheterized. Pulmonary capillary pressure is normal. Arterial unsaturation is present. On angiocardiology, a right-to-left shunt at the atrial level is present, there is delayed passage of contrast medium through the lungs, and the major pulmonary vessels narrow suddenly as they leave the hilum.

**THERAPY** Successful therapy for this disease awaits clarification of its etiology. The use of vasodilator drugs has been advocated and appears to have promise if the disease process is recognized during the stage of marked medial hypertrophy of the small pulmonary vessels and before excessive intimal proliferation has developed. Unfortunately, however, this stage frequently occurs before symptoms have developed. If vasodilators appear to improve the patient's condition, the advisability of a complete therapeutic bilateral pulmonary denervation should be considered.

**Patent Foramen Ovale with Ebstein's Malformation of the Tricuspid Valve** In this condition, the origin and structure of the tricuspid valve are abnormal, the septal leaflet arising well within the body of the right ventricle and not from the AV ring. Consequently, a portion of right ventricle is included in the right atrium and becomes thin-walled like the wall of this chamber. This produces a high incidence of ventricular and atrial arrhythmias. The tricuspid leaflets are usually thickened and the chordae tendinae are abnormally arranged. Both because of origin and structure, the flow of blood from the right atrium to the outflow tract and to the pulmonary artery is obstructed. The more extreme the valvular displacement, the greater the obstruction to the blood flow. Inflow or outflow obstruction increases filling pressure of the functioning right ventricle, which in turn increases right atrial pressure and produces a right-to-left shunt through a patent foramen ovale.

The signs and symptoms stem from either conduction disturbance or blood-flow obstruction. The repeated occurrence in a patient of supraventricular tachycardia, ventricular tachy-

cardia, or atrial flutter with varying block is suggestive. More commonly, however, the symptoms are those of exertional dyspnea and moderate cyanosis, with evidence of right ventricular failure. The heart is enlarged, the apex is displaced laterally, a bulge of the left chest may be present, but the precordium is surprisingly quiet. Murmurs are notoriously unpredictable. A short, rather insignificant basal systolic murmur is frequently associated with a mid-diastolic murmur heard low over the sternum or out toward the apex. The pulmonary 2d sound is usually split, but not accentuated. Fluoroscopically the right ventricle and right atrium are grossly enlarged, but the amplitude of pulsations is decreased. The main pulmonary artery segment is not enlarged, and the peripheral lung fields appear normally vascular. The ECG is not specific, though the common pattern is that of a small wide RSR' pattern in the right chest leads and a notched, slurred, shallow S wave over the left chest leads. Occasionally, however, the pattern is that of left ventricular hypertrophy or left BBB. The P wave is frequently peaked. The finding of a normal right ventricular and pulmonary artery pressure, associated with a lowered arterial oxygen saturation, suggests either Ebstein's malformation of the tricuspid valve or pulmonary arteriovenous aneurysm. A slow pullback maneuver from the right ventricle into the right atrium may establish the abnormal valvular position. In the angiocardigram, the right atrium appears grossly enlarged and empties slowly, and a right-to-left shunt at the atrial level may be present.

**THERAPY** There is no known corrective therapy for this malformation. Medical therapy should be directed toward the control of cardiac arrhythmias. The efficacy of digitalis, quinidine, Pronestyl, and atropine should be tested by trial and error.

**Secundum Defect with Acquired or Congenital Mitral Stenosis.** (Lutembacher's Syndrome). The life history of a septum secundum defect is accentuated and shortened by mitral stenosis which increases the pressure of the left atrium and thus increases the volume of left-to-right shunt, producing symptoms at an earlier date. The high frequency of a mid-diastolic rumble caused by relative tricuspid

atrium, the valve may be approached from the right chest, thus eliminating opening the left chest. The operation should be carried out using inflow occlusion and extracorporeal circulation.

### GROUP III: DEFECTS OF PULMONARY VENOUS DRAINAGE

Total anomalies of the pulmonary venous return are characterized by the drainage of both right and left pulmonary veins into a *common vein* which passes behind the heart and joins the systemic venous return at the level of (1) the superior vena cava, (2) the left innominate vein, (3) the right atrium, (4) the coronary sinus, or (5) the portal system below the diaphragm. The differential diagnostic points which are helpful in localizing the site of entry of the common pulmonary vein will be reviewed after a general discussion of the hemodynamic alterations.

Total anomalous pulmonary venous return to the right side of the heart must be considered separately from atrial defects of any type because of the difference in hemodynamics existing prior to birth. In the normal fetus, a significant volume of blood passes from the right ventricle through the lungs to the left atrium and ventricle. This volume augments blood flow from the right atrium to the left through the patent foramen ovale, so that the total left ventricular output approaches that of the right ventricle. When the pulmonary veins return to the right side of the heart, the volume of blood reaching the left side of the heart is greatly reduced. Consequently, the left ventricle and atrium are abnormally small, despite the fact that, after closure of the patent ductus arteriosus, they must accept the total responsibility for systemic flow. The volume of systemic blood flow in early infancy may be small but probably increases gradually as a result of right ventricular failure and increased right atrial pressure. After birth, the absence of venous return to the left atrium prevents left atrial pressure rise and foramen ovale closure, so that a *right-to-left shunt* through the foramen continues.

In contrast to the left ventricle, the fetal right ventricle handles a large volume of blood and consequently is abnormally thick and large. This increased blood volume perfuses the lungs following birth and closure of the

ductus. The major portion of blood returning to the right atrium passes again to the lungs because the small foramen ovale and small size of the left ventricle have increased the filling pressure of the left side of the heart. A pulmonary flow, many times that of systemic flow, develops within the first few minutes of life. Pulmonary pressure remains high since the volume of pulmonary blood flow is sufficient to utilize the major portion of the increased pulmonary vascular bed. Thick-walled pulmonary vessels persist, and pulmonary vascular disease develops early. High pulmonary blood flow and high pulmonary artery pressure result in early right ventricular failure and a hemodynamic alteration which has the beneficial effect of increasing right ventricular filling pressure and shunting a large volume of blood from the right atrium to the left. Unfortunately, right ventricular failure also increases pulmonary venous pressure and leads to a more rapid development of pulmonary vascular disease.

The large pulmonary blood flow which is present immediately after birth produces symptoms in infancy. Dyspnea, mild cyanosis, fatigability, and susceptibility of pulmonary infections are common. Early evidence of right heart failure and pulmonary congestion depend upon the degree of pulmonary vascular disease and the volume of pulmonary blood flow. Peripheral pulses are of poor quality during infancy, although they may be normal in the older child. There is a bulge of the left chest, and precordial activity is markedly increased. A strong apical impulse is felt across the lower precordium, and a forceful pulmonary second thrust is felt at the base. The apex of the heart is displaced laterally. A systolic murmur, suggestive of relative *pulmonic stenosis*, is usually present at the base of the heart. A mid-diastolic rumble near the apex, well transmitted into the left sternal border, suggests *relative tricuspid stenosis*. A long decrescendo diastolic blow indicative of *pulmonic insufficiency* may be heard along the left sternal border. The 2d sound is accentuated and split. In less than 50 per cent of patients there is a *continuous bruit*, soft and low-pitched in quality, over the site of entry of the pulmonary veins into the systemic circulation. Evidence of right heart failure and pulmonary congestion may be present. Under

atrium should be obtained close to the tricuspid valve as well as in the midatrium, for the position of the septal defect leads to the streamlining of blood from the left atrium into the right ventricle without atrial mixing, except close to the tricuspid valve. Pressure tracings from the left atrium suggest AV valve insufficiency. Right ventricular and pulmonary artery pressures are elevated frequently to the degree where a diagnosis of a large ventricular defect is suggested. Comparative dye-dilution studies from the left atrium and left ventricle establish whether an additional ventricular defect is present and constitute the only reliable method of determining whether the ventricular septum is intact or not. An angiocardigram reveals reopacification of the right side of the heart and frequently a small right-to-left shunt at the atrial level.

**THERAPY** Treatment of this malformation should be carried out in early childhood because of the relatively severe and rapidly progressive pulmonary vascular disease. Blind methods of closure are not applicable here since the valvular insufficiency must be corrected at the same time and must be done under direct vision. The septal defect is closed with an Ivalon sponge, and the cleft in the mitral or tricuspid valve is obliterated by sutures. If there is an associated ventricular defect, the septal leaflet of the tricuspid and mitral valve may be displaced inferiorly to join the ventricular septum, or an additional Ivalon sponge may be used. The latter procedure is indicated if displacement of the mitral septal leaflet is sufficiently marked to create aortic stenosis. If a widely cleft valve is present, a valvular graft may be necessary to prevent postoperative mitral and tricuspid stenosis.

**Septum Secundum Defect with Mitral Insufficiency** Mitral insufficiency may be produced by shortening of the chordae tendineae and faulty development of the mitral valve, although a cleft is not present and the defect does not extend to the AV ring. Signs and symptoms are similar to those of a septum primum defect and cleft mitral valve. The therapeutic approach is identical.

**Small Patent Foramen Ovale with Congenital Mitral Stenosis.** The principal alteration in hemodynamics is caused by the mitral stenosis and the increased pulmonary venous

pressure. The magnitude of the left-to-right shunt is reduced by the small size of the partially closed foramen ovale. The pattern of pulmonary hypertension is complicated by venous congestion, capillary dilatation, thickening of the alveolar walls, and the presence of pulmonary edema because of increased pulmonary venous pressure prior to birth. The left atrium is large when the foramen ovale is of moderate size, but when the foramen ovale is barely patent, the left atrium is abnormally small since fetal right ventricular blood flow is directed almost totally through the ductus because of the increased pulmonary venous resistance.

The changes occurring in the lungs before birth make extremely difficult the shift from reliance on the placenta to reliance on the lungs for gaseous exchange. The newborn infant appears acutely ill, cyanosis due to right heart failure and faulty gaseous diffusion appears early, pulmonary hypertension is severe. The peripheral pulses are poor, the apex of the heart is displaced laterally. Murmurs may be present, suggesting mitral stenosis possibly combined with insufficiency. There is evidence of right heart failure and pulmonary congestion. Under the fluoroscope, the lungs appear vascular and congested. The right side of the heart is enlarged, the left ventricle is normal, and the left atrium is normal or enlarged. Right ventricular strain is revealed by the ECG. Contrast solution traverses the lungs slowly, and there may be reopacification of the left atrium with each beat of the heart, indicating mitral insufficiency. The obstructed mitral orifice, as well as a small left-to-right shunt across the foramen ovale, may also be seen. Pulmonary artery pressure is markedly increased, and a high pulmonary wedge pressure is found, which indicates severe pulmonary venous obstruction.

**THERAPY** Correction of this malformation, though extremely hazardous, must be undertaken in early infancy. The outcome is dependent upon the magnitude of pulmonary vascular disease and the exact type of mitral obstruction. Little can be done if the mitral ring is abnormally small and the valve itself is normal. However, if there has been fusion of the leaflets of the mitral valve, it may be possible to open the valve. Because of the size of the patent and the size of the left

alous pulmonary drainage because there is a narrowing of the common pulmonary vein as it passes through the diaphragm, which adds the factor of pulmonary venous obstruction to the total picture. Capillary and alveolar changes occur prior to birth, which cause a barrier to gaseous diffusion immediately after birth. Infants with this anomaly appear cyanotic within hours after birth. Cyanosis and dyspnea increase rapidly. There may be early evidence of right heart failure. Murmurs are usually absent. The pulmonary 2d sound at the base of the heart is *accentuated* and *split*, and an *early diastolic murmur* of pulmonary insufficiency may be present along the left sternal border. The lungs are usually clear. In addition to the enlargement of the right side of the heart and the main pulmonary artery segment as seen by x-ray, the lungs have a finely granular appearance similar to that caused by severe congestion in acquired mitral stenosis. There is laboratory evidence of a right-to-left shunt at the atrial level, and occasionally of reopacification of the inferior vena cava after passage of the contrast medium through the lungs.

**THERAPY.** Therapy for this malformation must be undertaken in the first weeks of life because life expectancy is short and the development of pulmonary vascular disease is rapid. Unfortunately, the diagnosis is usually made at the autopsy table. If diagnosed early, however, correction of the defect with closure of the patent foramen ovale should be possible.

#### GROUP IV: MALFORMATIONS WITHOUT A COMMUNICATION BETWEEN THE SYSTEMIC AND PULMONARY CIRCULATIONS

**Lesions of the Left Side of the Heart without Elevated Pulmonary Venous Pressure at Birth**

**Coarctation of the Aorta.** This malformation is characterized by an extreme narrowing of the lumen of the aorta immediately distal to the origin of the left subclavian artery at the point of the insertion of the ductus arteriosus. The obstruction to aortic blood flow places a strain upon the left ventricle, and the arterial blood pressure proximal to the coarctation is elevated. Vascular pathways connecting the proximal and distal aortic segments form a large network of *collateral arterial ves-*

*sels* and increase the blood flow to the lower extremities. Circulatory embarrassment is rare during infancy. In a few patients, when the entire load of maintaining the systemic circulation against a high resistance is placed on the left ventricle, congestive failure may appear after closure of the ductus. Death may result, or the patient may develop sufficient left ventricular hypertrophy to reestablish cardiac compensation. In most patients, symptoms are absent during childhood, and the malformation is suspected for the first time when *arterial hypertension* is discovered during a routine physical examination. There is a surprising sex distribution which confines this malformation to *males* by a very large percentage. Because blood flow is increased to the upper extremities and decreased to the lower extremities, the patient with a coarctation of the aorta has broad shoulders, a well-developed chest, and relatively narrow hips.

Early symptoms are *pains and cramps in the legs*, numbness, cold lower extremities, and frequently severe *headaches*. The advanced symptoms are those of severe hypertension or congestive failure.

The pathognomonic physical finding of coarctation of the aorta is the *absence or weakening of the femoral artery pulse* and a decrease in femoral artery systolic pressure. In contrast to the sharp forceful radial pulse, the femoral pulse feels dampened, has a narrow pulse pressure and a late peak because of prolonged ascending and descending limbs of the pulse wave. Pulsations of the abdominal aorta are also weak or absent. A *systolic murmur*, loudest during midsystole, is heard at the base of the heart and along the spine posteriorly. The midsystolic timing suggests that the murmur arises outside the heart. In older individuals, *continuous or systolic bruits*, which suggest a markedly increased collateral blood flow, may be heard over the intercostal vessels, along the course of the internal mammary vessels, or in the axilla. The *aortic 2d sound is increased in intensity*. Not infrequently, there is a *decrecendo diastolic murmur*, maximal over the aortic valve area and heard along both sides of the sternum, which suggests aortic insufficiency and an associated congenital bicuspid aortic valve. Enlarged intercostal vessels may be palpated over the chest.

the fluoroscope, the right side of the heart and the pulmonary artery are enlarged, and the pulmonary vascular markings are increased. The aorta may be small. The ECG reveals right axis deviation and a right BBB pattern suggestive of combined diastolic and systolic overload of the right ventricle. The presence of a uniform oxygen content in blood samples from the right atrium through the right side of the heart and including systemic arteries is pathognomonic. Pulmonary artery pressure is elevated, systemic pressure is low. In the angiocardigram there may be a filling defect at the site of entry of the anomalous pulmonary veins, and both right and left sides of the heart opacify simultaneously. Reopacification of the right side of the heart occurs after circulation of the contrast medium through the pulmonary vascular bed.

**THERAPY** Total correction of this malformation includes closure of the foramen ovale and the creation of a sufficiently large anastomosis between the common pulmonary vein and left atrium to prevent obstruction of the pulmonary venous return. It is difficult to make a sufficiently large anastomosis unless the right atrium is opened. The atrial septum is incised, and the common pulmonary vein, which lies immediately posteriorly to the left atrium, is anastomosed to the left atrium from within the left atrial cavity, utilizing a long incision parallel to the course of the common pulmonary vein. In part, the success of the correction is dependent upon the ability of the underdeveloped left side of the heart to handle an increased systemic blood flow. Unfortunately, accurate estimation of systemic blood flow prior to surgery is extremely difficult since a true mixed venous sample from the systemic circulation cannot be obtained. Correction of the defect should be carried out before excessive pulmonary vascular disease has developed. Inflow occlusion and an extracorporeal circulation are necessary adjuncts to the surgical procedure. Care must be taken to drain bronchial artery blood flow from the lungs during the period that the common pulmonary vein is closed and thus prevent pulmonary hemorrhage. Left heart failure may be avoided by closing the atrial defect with an Ivalon sponge which contains several 4-mm holes in order to permit decompression of the left atrium. Experimental evi-

dence suggests that these holes will endothelialize within few days and thus complete the closure.

**Total Anomalous Pulmonary Venous Return to the Superior Vena Cava.** In this malformation, the common pulmonary vein usually enters the superior vena cava close to the entry of the azygos vein. A continuous murmur may be heard to the right of the midline in the 2d and 3d interspace. Under the fluoroscope, there is a prominent bulge of the superior vena cava. Cardiac catheterization reveals a sudden increase in oxygen content in the superior vena cava above the insertion of the cava into the right atrium. With angiocardigraphy, there is reopacification of the superior vena cava after the contrast medium has passed through the lungs.

**Total Anomalous Pulmonary Venous Return to the Left Innominate Vein.** This malformation may be differentiated radiographically from the insertion of the common pulmonary vein into the superior vena cava by means of a bulge, which gives the heart a figure-of-eight appearance that is seen above the level of the main pulmonary artery segment both to the left and right of the midline. There is an increased oxygen content of blood sampled from the bulge, and this area reopacifies in the angiocardigram.

**Total Anomalous Pulmonary Venous Return to the Right Atrium.** The differentiation of this malformation from a large atrial septal defect is difficult. The correct diagnosis depends upon the demonstration of a common oxygen content in the right atrium, right ventricle, pulmonary artery, and aorta, bidirectional shunt at the atrial level, and simultaneous filling of the pulmonary artery and aorta.

*Total Anomalous Pulmonary Venous Return to the Right Atrium*

The common pulmonary vein enters the coronary sinus, causing a localized bulge of the right atrial contour. There is reopacification of the coronary sinus following the passage of contrast solution through the lungs. An increase in oxygen content of the blood of the coronary sinus is demonstrated by cardiac catheterization.

**Total Anomalous Pulmonary Venous Drainage into the Portal System.** The clinical syndrome associated with this malformation is totally different from other varieties of anomalous pulmonary venous drainage.

symptoms of early left heart failure. Surgery should not be delayed unduly for congenital aortic stenosis causes sudden death in about 10 per cent of patients.

**Subaortic Stenosis.** In this malformation, the aortic valve is normal. Immediately proximal to the aortic valve, a fibrous band partially occludes the outflow tract of the left ventricle. Subaortic stenosis simulates valvular aortic stenosis for the signs and symptoms are identical, and differential diagnosis is difficult. A clearly split 2d sound at the base of the heart suggests subaortic rather than aortic stenosis. Poststenotic dilatation of the ascending aorta occurs in both. However, in valvular stenosis, the dilatation is distal to the sinuses of Valsalva and a clear incisura is seen on x-ray which separates the right atrium from the ascending aorta. In subaortic stenosis, the dilatation extends right to the valve ring, thus obscuring the incisura. Left heart catheterization may establish the diagnosis if, on pullback into the left ventricle, one can demonstrate an area of systolic pressure equal to that of the aorta and a diastolic pressure of zero.

**THERAPY** The therapeutic approach to this malformation is the excision of the subaortic band through the ascending aorta under direct vision, using inflow occlusion and extracorporeal circulation.

**Anomalous Origin of the Left Coronary Artery from the Pulmonary Artery.** This is a rare deformity in which the left coronary artery arises from the pulmonary artery. Blood to the left myocardium has a lower oxygen content, and when pulmonary artery pressure is normal, the perfusion pressure is too low to be effective. During left ventricular contraction, the pressure applied to the outer wall of the intramyocardial coronary arteries exceeds intravascular pressure and blood may be forced back into the pulmonary artery. The rate of perfusion is thus greatly reduced, and myocardial ischemia and infarction may result. Signs and symptoms are absent at birth because pulmonary artery pressure is high. It is only when pulmonary artery pressure drops and the difference between systemic and pulmonary pressure becomes significant that myocardial ischemia develops. Symptoms usually occur between the second and sixth month, and death follows relatively rapidly. The symptoms are of two types. Attacks may be brought

on by a meal and are characterized by intense precordial pain accompanied by pallor, cyanosis, cold perspiration, and rapid respirations. On the other hand, initial symptoms may involve only the respiratory apparatus, leading to the frequent diagnoses of pneumonia. Combined heart failure may be present. The heart is large and quiet; heart tones are poor and distant, and murmurs are seldom heard. The apical heart beat is difficult to feel, and heart sounds over the right ventricle are louder than those over the left. Under the fluoroscope, the left ventricle and left atrium appear huge. Pulsations of the left ventricle may be difficult to see. The electrocardiographic pattern may be one of left heart strain or may suggest a myocardial infarct. Characteristically, the T waves are deeply inverted in the standard limb and left precordial leads, and the amplitude of the QRS complex is reduced. Occasionally, a deep Q wave may be present in leads I and aVL and a QS pattern may be seen in the left chest leads. The origin of the left coronary from the pulmonary artery has been demonstrated by angiocardiology. The left ventricle appears large and thin-walled in contrast to the small-chambered, thick-walled left ventricle of endocardial fibroelastosis.

**THERAPY.** The surgical correction of this anomaly may be possible provided that the diagnosis can be made early enough and adequate perfusion of the left coronary vessel can be maintained during the anastomosis of the left coronary vessel to a systemic artery. Ligation of the left coronary or the use of talc in the pericardium has been of some success, but the long-term prognosis would not appear so good as if an adequate flow through the anomalous coronary could be brought about by an anastomosis.

**Endocardial Fibroelastosis.** It has not been definitely established whether or not this condition represents a congenital malformation.<sup>11</sup>

The etiology may well be metabolic rather than a specific congenital malformation. There is a marked thickening of the endocardium, of the left ventricle, of the left atrium, and occasionally of the right side of the heart. Elastic fibers are abundant and infiltrate adjacent myocardium. The myocardium is greatly hypertrophied. The thickened endocardium and hypertrophied myocardium suggest that the mechanism is similar to that of con-

<sup>11</sup> See Part 18, Chaps 12 and 13 Editor.

Fluoroscopic examination reveals an enlargement of the left ventricle, anterior rotation of the apex, and a boot-shaped heart. The main pulmonary artery segment is not well visualized in the PA position. A careful study of the base of the heart, with the patient in a slight LAO view and with the esophagus filled with barium, frequently reveals the area of coarctation and poststenotic dilatation. In children over the age of 10, *scalloping of the lower ribs* may be seen on x-ray, which indicates erosion of the inferior margin of the rib by the enlarged and tortuous intercostal vessels. The ECG may be normal or may give evidence of left ventricular hypertrophy. Angiocardiology and cardiac catheterization are seldom necessary to establish the diagnosis. When the length of the narrow aortic segment is in question, a *retrograde aortogram* offers the best means of defining the obstruction.

**THERAPY** The long-term success of surgical resection of aortic coarctations warrants operation for the child, even though the patient may be completely asymptomatic. Prolonged hypertension causes progressive arteriosclerotic changes proximal to the coarctation, so that surgery should be advised during childhood. The optimal time for correction is 8 to 15 years of age, but in the presence of severe congestive failure, surgery may be carried out at any age. The use of a graft may be necessary if the coarcted segment is long.

A special therapeutic problem concerns the infant with a simple coarctation and severe congestive failure. All measures for the medical treatment of congestive failure should be attempted first and a period of watchful waiting advised. If failure reappears, early surgery is mandatory.

**Aortic Stenosis.** Congenital valvular aortic stenosis occurs more frequently than previously thought. During childhood, the valve is thickened, rubbery, and fibrous, with leaflets which are partially or totally fused. During adulthood, calcification occurs and the anatomic differential diagnosis between rheumatic and congenital aortic stenosis becomes difficult, if not impossible. Stress placed on the left ventricle increases with the passage of time because progressive changes in the valve increase the degree of stenosis, and there is a steady increase in cardiac output as the patient

grows and develops. A stenosis, which is of little significance while cardiac output is low, becomes highly significant if cardiac output is doubled or tripled. This accounts for the common appearance of symptoms near the age of puberty.

Symptoms are absent until failure of the left ventricle occurs. The common symptoms are fatigue, exertional dyspnea, and occasionally *syncope* or precordial pain. The peripheral pulses are full and equal, and the pulse pressure is normal in the asymptomatic patient; in the patient with symptoms, however, the pulse wave is slow and the pulse pressure is narrow. A forceful apical impulse felt to the left and below the site of the normal apical beat is present. A *systolic thrill* is palpable at the base and frequently extends into the neck. A loud, long, frequently high-pitched *systolic murmur* is heard in older patients in the 1st and 2d right interspace and is well transmitted to the neck. During infancy, the murmur is maximal in the 3d and 4th left interspace, suggesting the diagnosis of ventricular defect. As the child grows, the murmur becomes louder at the base, first to the left and then to the right of the sternum. A long systolic murmur extending throughout systole suggests greater obstruction than a short and coarse systolic murmur. The 2d sound at the base of the heart is clear. Under the fluoroscope, the apex of the heart is rounded and anteriorly rotated so that, in the PA projection, the pulmonary artery area is concave and the ascending aorta is prominent. If there is left heart failure, the left atrium may be enlarged. The ECG reveals left ventricular hypertrophy. Left heart catheterization, when the catheter is passed through the aortic valve, confirms the presence of a *pressure gradient across the aortic valve*.

**THERAPY.** Surgical correction is best accomplished using inflow occlusion and direct vision of the valve through the open ascending aorta with either *hypothermia* or an *extracorporeal circulation*.<sup>10</sup> Great care must be taken to incise the valve down to the valve ring along the line of the commissure in order to avoid significant postoperative aortic insufficiency. Indications for surgery are the progressive development of left ventricular hypertrophy or strain in the ECG and the appearance of

<sup>10</sup> See also Part 7, Chap. 16, Editor

*trophy*. The striking finding in an angiocardio-gram is the *slow passage of contrast medium through the lungs* and the retention of a large volume of radiopaque material in the greatly enlarged left atrium. Repeated reopacification of the left atrium suggests significant mitral insufficiency. Cardiac catheterization is of little value. Pulmonary wedge pressure is elevated.

**THERAPY.** The successful surgical correction of this malformation depends upon the type of mitral stenosis which is present. Little can be done for the patient if the mitral valve ring is markedly reduced in size. However, if the stenosis is primarily due to fusion of the commissures, a mitral commissurotomy may be helpful. Inflow occlusion and extracorporeal circulation should be used, so that the malformed valve can be visualized readily. Early surgery should be advised because of the rapidly progressive pulmonary vascular disease.

#### *Cor Triauriculare*

In this malformation, the embryonic common pulmonary vein fails to be absorbed into the wall of the left atrium, and the junction of this common vein with the atrium is stenotic. Increased pressure in the common vein invaginates it into the left atrium, producing a formation like an appendage within the atrium. The stenotic orifice of the vein takes a position close to the mitral valve and produces the clinical picture of mitral stenosis.

A *foramen ovale* is usually present and opens into the lower or true left atrial chamber. Occasionally, the upper chamber and right atrium may be connected by an anomalous pulmonary vein or window opening. More rarely, the upper chamber is blind, except for an opening into the right atrium, and blood from the pulmonary veins reaches the left ventricle after traversing the upper left atrial chamber, thence through the atrial defect into right atrium, and then via the foramen ovale into the lower left atrial chamber, and finally through the mitral valve into the left ventricle.

The clinical findings are those of mitral stenosis associated with either advanced *pulmonary vascular disease* or episodes of *acute pulmonary edema*, depending upon the severity of the stenosis. A bulge of the left chest is present. There is an *apical mid-diastolic rumble* with presystolic accentuation. Systole is clear. A *decreased diastolic murmur* of pulmonary insufficiency may be heard along the left sternal border. There is enlargement of the right side of the heart and the left atrium

under the fluoroscope. In contrast to congenital and acquired mitral stenosis, the left auricular appendage is not enlarged since the inner wall of the left atrium formed by the common pulmonary vein does not include the latter. The ECG shows a right ventricular hypertrophy. Pulmonary arterial and pulmonary wedge pressures are elevated. A significant *pressure gradient* between pulmonary arterioles (pulmonary wedge pressure) and left atrium indicates some form of *pulmonary venous obstruction*.

**THERAPY.** Prognosis with surgery should be excellent, for the release of the stenotic common pulmonary vein outlet reestablishes a normal circulation without injury to the mitral valve. Surgery should be advised as early as possible for the optimal prognosis is limited by the progressive development of pulmonary vascular disease.

**Congenital Pulmonary Venous Obstruction.** This malformation may be a primary congenital defect or the result of endocardial fibro-elastosis. It may involve all or only one of the pulmonary veins. Damage to the parenchyma of the lung from elevated venous pressure may occur before birth, shortly after birth, or later, depending upon the severity and the number of veins involved. The symptoms are those of *cor pulmonale*: progressive exertional dyspnea, fatigability, episodes of hemoptysis, and right heart failure. There is a bulge of the left chest and increased amplitude of right ventricular contractions. Murmurs are usually absent, however, a *systolic murmur* of relative pulmonary stenosis and a *diastolic murmur* of pulmonary insufficiency may be heard along the left sternal border. The *2d heart sound is loud and split*. Under the fluoroscope, only the right side of the heart is enlarged. The lung fields usually appear clear, but there is enlargement of the main pulmonary arteries. The ECG reveals *systolic overload of the right ventricle*, and the *tall P waves* of right atrial hypertrophy may be present. The angiocardio-gram demonstrates the slow passage of contrast medium through the lungs and a *normal-sized left atrium*. Pulmonary artery and pulmonary wedge pressures are markedly elevated.

**THERAPY.** The therapeutic approach to this malformation is based on early diagnosis and early surgical relief of the pulmonary venous stenosis. The success is entirely dependent upon the time at which the diagnosis is made,

strictive pericarditis in that the left ventricle cannot reduce its chamber size during contraction and expel blood during systole because of the dense endocardium. End diastolic pressure is high, and systolic pressure is low.

The onset of symptoms occurs most frequently during the first six months of life and, in 95 per cent of cases, during the first year. The most common presenting complaint is pneumonia. Signs of left and right heart failure are present. The heart is grossly enlarged, but the precordium is quiet. Heart tones are normal or reduced. Murmurs arising from the mitral valve, and occasionally from the aortic valve, are frequently present and help to differentiate this lesion from anomalous origin of the left coronary artery. An apical systolic murmur is most common. A triple (gallop) rhythm may be present. Under the fluoroscope, the heart appears grossly enlarged, with primary enlargement of the left ventricle and left atrium. Cardiac activity is decreased, and the lungs frequently appear congested. The ECG shows severe left heart strain and marked left ventricular hypertrophy. A delayed passage of contrast medium through the lungs, an enlarged left atrium, and large, very thick-walled left ventricle are seen in the angiocardiogram. Pulmonary arterial and pulmonary wedge pressures are of little value. The chief differential diagnostic findings to distinguish this malformation from anomalous origin of the left coronary artery are marked left ventricular hypertrophy and strain in the ECG, and a thick-walled, small-chambered left ventricle visualized by angiocardiology.

**THERAPY** The efficacy of treatment cannot be judged since it is extremely difficult to prove the diagnosis without an autopsy. Medical treatment consists of antibiotics, digitalis, mercurial diuretics, low salt diet, and oxygen. The response to digitalis is sometimes dramatic. It now seems clear that there is a real chance for recovery if the infant survives the first attack of failure and responds well to digitalis. Repeated attacks of pneumonia and left heart failure occur in infancy, but over a period of years the attacks decrease and may eventually disappear. Whether this improvement results from a decrease in thickness of the endocardium or increased efficiency of the left ventricle is not clear.

The surgical approach, which theoretically

offers the best chance of physiologic correction, is an *endocardectomy* which, just as a *pericardectomy* for constrictive pericarditis, restores normal function. However, the question of mural thrombus formation, embolization, and recurrence of endocardial scarring remains to be answered.

### LEFT-SIDED LESIONS ALWAYS ASSOCIATED WITH AN ELEVATED PULMONARY VENOUS PRESSURE

**Congenital Mitral Stenosis.** Isolated congenital mitral stenosis is rare, for some degree of mitral insufficiency is almost always present. The malformed mitral valve has abnormally shortened chordae tendineae, fused commissures, thickened valve leaflets, and frequently, an abnormally small valve ring.

When stenosis is severe, increased pulmonary venous pressure is present prior to birth, and fetal pulmonary hypertension is retained and complicated by *alveolar and capillary wall thickening*, with resultant diffusion difficulty. Extreme dyspnea, fatigability, cyanosis, and the early onset of right-sided congestive failure without evidence of pulmonary congestion characterize this syndrome. When stenosis is less severe, vascular and parenchymal changes do not occur prior to birth, for the mitral valve can accommodate the small fetal pulmonary blood flow. After birth, the rapidly increasing pulmonary blood flow makes the mitral stenosis progressively more significant. Pulmonary venous hypertension develops, and in addition to the findings of right heart failure, the clinical pattern is characterized by episodes of severe *pulmonary edema*.

In most patients, an *apical systolic murmur* indicative of some degree of mitral insufficiency is present, in addition to the *diastolic rumble* of mitral stenosis. The 2d heart sound at the base is *accentuated and split*, and a *decrecendo diastolic murmur* of pulmonary insufficiency is frequently heard along the left sternal border. Under the fluoroscope, the heart presents an enlargement involving primarily the left atrium and right ventricle. Left ventricular enlargement is also present if mitral insufficiency is significant. The lung fields appear congested. The pulmonary arteries are enlarged. The electrocardiographic pattern is that of *right ventricular hypertrophy* and a wide notched P wave suggestive of left atrial enlargement.

## 6-80 CONGENITAL HEART DISEASE

of the major pulmonary arteries, which may be congenital in origin or represent healed thrombi. The most striking physical finding is a *loud, long systolic murmur, heard over the entire pulmonary bed* and which, in certain areas, may be *continuous*. The pulmonary 2d sound at the base of the heart may be either accentuated or normal. Evidence of right ventricular hypertrophy and right heart failure may be present if the total sum of stenotic areas is great.

The diagnosis of this malformation is best

confirmed by angiocardiology, for with filling of the pulmonary arterial trunk, the multiple areas of stenosis stand out. Pressure gradients may be found within the larger pulmonary vessels indicative of some degree of peripheral stenosis.

**THERAPY.** In patients in whom the stenosis is membranous and immediately distal to the pulmonary valve, excision of the stenotic area may be curative. When the areas of stenosis are multiple, the best that can be achieved is the relief of the most extreme sections.

strictive pericarditis in that the left ventricle cannot reduce its chamber size during contraction and expel blood during systole because of the dense endocardium. End diastolic pressure is high, and systolic pressure is low.

The onset of symptoms occurs most frequently during the first six months of life and, in 95 per cent of cases, during the first year. The most common presenting complaint is pneumonia. Signs of left and right heart failure are present. The heart is grossly enlarged, but the precordium is quiet. Heart tones are normal or reduced. Murmurs arising from the mitral valve, and occasionally from the aortic valve, are frequently present and help to differentiate this lesion from anomalous origin of the left coronary artery. Whether this improvement results from a decrease in thickness of the endocardium or increased efficiency of the left ventricle is not clear.

The surgical approach, which theoretically

offers the best chance of physiologic correction, is an *endocardectomy* which, just as a pericardectomy for constrictive pericarditis, restores normal function. However, the question of mural thrombus formation, embolization, and recurrence of endocardial scarring remains to be answered.

### LEFT-SIDED LESIONS ALWAYS ASSOCIATED WITH AN ELEVATED PULMONARY VENOUS PRESSURE

**Congenital Mitral Stenosis.** Isolated congenital mitral stenosis is rare, for some degree of mitral insufficiency is almost always present. The malformed mitral valve has abnormally shortened chordae tendineae, fused commissures, thickened valve leaflets, and frequently, an abnormally small valve ring.

When stenosis is severe, increased pulmonary venous pressure is present prior to birth, and fetal pulmonary hypertension is retained and complicated by alveolar and capillary wall thickening, with resultant diffusion difficulty. Extreme dyspnea, fatigability, cyanosis, and the early onset of right-sided congestive failure without evidence of pulmonary congestion characterize this syndrome. When stenosis is less severe, vascular and parenchymal changes do not occur prior to birth, for the mitral valve can accommodate the small fetal pulmonary blood flow. After birth, the rapidly increasing pulmonary blood flow makes the mitral stenosis progressively more significant. Pulmonary venous hypertension develops, and in addition to the findings of right heart failure, the clinical pattern is characterized by episodes of severe pulmonary edema.

In most patients, an apical systolic murmur indicative of some degree of mitral insufficiency is present, in addition to the *diastolic rumble* of mitral stenosis. The 2d heart sound at the base is *accentuated* and *split*, and a *decreasing diastolic* murmur of pulmonary insufficiency is frequently heard along the left sternal border. Under the fluoroscope, the heart presents an enlargement involving primarily the left atrium and right ventricle. Left ventricular enlargement is also present if mitral insufficiency is significant. The lung fields appear congested. The pulmonary arteries are enlarged. The electrocardiographic pattern is that of *right ventricular hypertrophy* and a wide notched P wave suggestive of *left atrial hyper-*

setting up the above-described irritative phenomena in the capillaries of the skin.

The time that elapses between the injection and the detection of the ether smell in the nose represents the arm-to-lung time which, in normal individuals and in those suffering from heart failure, is only a fraction of the arm-to-tongue time as measured by the saccharin, Decholin, or calcium methods. The interval between the injection of ether and the first appearance on the face of these unpleasant stinging and tingling sensations (which may last only a few seconds) is known as the *arm-to-facial-paresthesia time*. Although the paresthesias are usually confined to the face, they may appear in the scalp or may become generalized, especially in children, where they can extend centrifugally to distant portions of the body. In children, more so than in adults suffering from congenital heart disease, the severity of this cutaneous reaction is proportional to the quantity of ether injected, the most dramatic reaction being obtained when a fuller dose of 5 to 10 minims of ether is employed. The facial paresthesias usually appear at a time coincident with the detection of ether by smell, giving an arm-to-facial-paresthesia time which is equal to the arm-to-lung time. The arm-to-facial-paresthesia time may also precede or follow in point of time the arm-to-lung time. The arm-to-lung time may, however, register simultaneously with the abbreviated arm-to-tongue time, or it may actually follow the latter. If so, this would cause an alteration of the normal relationship between the arm-to-lung time and the arm-to-tongue time. Its fractional arithmetic relationship may thus become altered in right-to-left shunt from a ratio of 1:2 or 1:3, in "normals," to a ratio of 1:1 or 1+:1, in right-to-left shunts.

Positive *paresthesia times* have been obtained in patent ductus arteriosus with complete reversal of the shunt. In three cases of patent ductus arteriosus with a reversed shunt observed by the author, the paresthesias were striking in the lower half of the body of one case, especially in the toes. This is plausible since, as Burchell (1946) has pointed out, more unsaturated (right ventricular) blood reaches the lower than the upper half of the body in this congenital condition. Apparently

not enough test substance reaches the conventional signal area to give the classic response. In two other similar cases, the facial paresthesias did dominate exclusively, there was undoubtedly sufficient short-circuiting of gaseous ether through a coexisting atrial defect or ventricular defect to trigger off the signal area.

*Use of Circulation Times for Localization of Septal Defects during Cardiac Catheterization.* The presence of abbreviated circulation time with saccharin or Decholin in congenital heart disease gives only *presumptive* evidence of the presence of a right-to-left shunt. However, the mere qualitative appearance of paresthesias in the course of performing the ether test offers *conclusive* evidence that a right-to-left shunt exists. Obviously the time measurement before paresthesias appear plays no role in such diagnostic conclusion. Valuable as the above conventional methods are, the use of tracer substances injected into a peripheral vein offers inadequate means for the localization of an intracardiac right-to-left shunt. However, when these methods are carried out through catheterization, septal defects can be readily localized. Through such means it has become possible to differentiate between the tetralogy of Fallot (with an overriding aorta) and pulmonary valvular stenosis with intact ventricular septum and a patent foramen ovale or an atrial septal defect.

Cardiac catheterization has, therefore, opened new avenues for the differential diagnosis of shunts in congenital heart disease.

The right ventricle-to-systemic-arterial-capillaries time can be determined by the following methods:

*Objective Method for Diagnosis of Right-to-left Shunt. FLUORESCEN METHOD (RIGHT VENTRICLE-TO-FACE TIME)* Ziegler has employed fluorescein and ultraviolet light to establish the right ventricle-to-face time. With the catheter in the outflow tract of the right ventricle, a 5 per cent fluorescein with a 5 per cent sodium bicarbonate solution is injected slowly in an amount previously calculated just to fill the entire catheter. An additional amount measured roughly in proportion to body weight is then injected as rapidly as possible. The time that elapses from the beginning of the injection to the appearance of the fluorescence in the ocu-

for if advanced pulmonary vascular disease has occurred, little can be gained.

**Corrected Transposition of the Great Vessels with Insufficiency of the Left-sided Atrioventricular Valve.** Insufficiency of the left-sided tricuspid (functional mitral) valve may be of two types. Most commonly, Ebstein's malformation of the valve is present, characterized by the anomalous origin of the septal leaflet from the wall of the systemic ventricle rather than from the AV ring and by malformed shortened chordae tendineae. In contrast to the right ventricle of the classic Ebstein's malformation, the left or systemic ventricle is not abnormally thin, except in the area of ventricle included in the left atrium. Less commonly, the left-sided AV valve is insufficient because of marked shortening of the chordae tendineae, thickening and rolling of the valve leaflets, and anomalous adhesions to the wall of the ventricle. When insufficiency is severe, pulmonary changes occur before birth and persist after birth, the course is acute, cyanosis is present if the foramen remains patent, and failure of the right ventricle occurs early. When insufficiency is less severe, the course is characterized by episodes of acute pulmonary edema and the gradual production of severe pulmonary vascular disease followed by right ventricular failure and death. The physical findings suggest mitral insufficiency. There is frequently a bulge of the left chest. The apical impulse is displaced laterally and inferiorly, indicating left ventricular enlargement. An apical systolic murmur suggests mitral insufficiency. On fluoroscopy, there is marked enlargement of the left atrium and ventricle. Systolic pulsations of the left atrium are easily seen. The lung fields may appear congested. The ECG reveals frequently a partial or complete AV block, in addition to the findings of left . . .

The  
there

ciency in early childhood. Proof of the malformation depends upon the establishment of the transposed origin of the aorta and pulmonary artery by angiocardiology or cardiac catheterization. The aorta arises anteriorly and somewhat to the left of the pulmonary artery and frequently produces a straight contour to the left heart border. The pulmonary artery arises in the midline. During cardiac cath-

terization, the course of the catheter follows a more median position and reaches the pulmonary artery well to the right of the left heart border. Pulmonary artery and pulmonary wedge pressures are usually elevated. Evidence of a shunt is lacking, unless the valvular deformity is associated with a septal defect.

**THERAPY.** There is no known therapy for this malformation. In the presence of severe pulmonary congestion, the Cutler procedure might be of practical value. An anastomosis between the azygos vein and a pulmonary vein might serve to decompress the pulmonary venous engorgement by transmitting stress to the systemic venous system and thus relieve the frightening symptoms of pulmonary edema and protect the embarrassed respiratory function.<sup>11</sup>

## RIGHT-SIDED LESIONS

**Valvular Pulmonary Stenosis with Intact Ventricular Septum and Closed Foramen Ovale.** This malformation differs from isolated pulmonary stenosis with patent foramen ovale in that there is no right-to-left shunt. Cyanosis is absent, except as a manifestation of congestive heart failure. The clinical syndrome is described under isolated valvular pulmonary stenosis associated with a patent foramen ovale.

**Isolated Infundibular Pulmonary Stenosis with Intact Ventricular Septum and Closed Foramen Ovale.** Except for the absence of cyanosis, this condition does not differ from isolated infundibular pulmonary stenosis associated with patent foramen ovale.

**Primary Pulmonary Hypertension with Closed Foramen Ovale.** This entity is similar to pulmonary hypertension associated with patent foramen ovale, except for the absence of a right-to-left shunt through the foramen ovale.

**Coarctation of the Pulmonary Arteries.** Coarctation of the pulmonary arteries may be divided into two types, the first consisting of a membranous stenosis just distal to the pulmonary valve. In this instance, the findings are similar to those of isolated valvular pulmonary stenosis, except for the remarkable distribution of the basal systolic murmur throughout both lung fields. The second type consists of extensive and multiple constrictions

<sup>11</sup> See Chap. 14 Editor.

## 6-84 CONGENITAL HEART DISEASE

The curves obtained varied with the site of the defect. In the absence of any left-to-right shunt, rapid injection of an indicator into the left atrium, left ventricle, or thoracic aorta yielded a primary curve with a sharp rapid ascent and a slightly slower descent. An injection proximal to the ventricular defect shunted off some of the dye through the pulmonary

circulation and caused an abrupt decline in rate of fall in concentration. An injection distal to the site of shunt gave a normal curve. This selective injection of indicator into various sites would lead to dilution curves characteristic of the location of the defect and thereby to more precise localization of the left-to-right shunt.

# Circulation time in congenital heart disease

WILLIAM M. HITZIG

Circulation-time studies not only have served well as screening tests but have contributed considerably to greater understanding of the circulatory dynamics in congenital heart disease. Initially employed only for the gross determination of the presence or absence of venoarterial shunt, they subsequently helped to substantiate the findings of angiocardiology and catheterization. They have supplied information helpful in differentiating cases with intact septa from others where they were perforated. For example, in cases where cyanosis and clubbing may be prominent features, such as pulmonary carcinoma or pulmonary hypertension without shunt, circulation times have been useful in distinguishing these conditions from syndromes with a right-to-left shunt. The latter include:

- 1 Tetralogy of Fallot or Eisenmenger's complex with an overriding aorta
- 2 Pulmonary valvular stenosis with an interatrial septal defect
- 3 Interatrial septal defect with pulmonary hypertension and sclerosis
- 4 Patent ductus arteriosus with reversal of flow

McGraw and Goldman were the first to show that, in certain types of congenital heart disease, the arm-to-carotid-sinus time was considerably abbreviated. They regarded this as characteristic of venoarterial shunt, since the substance employed presumably passed from the right heart into the systemic circulation by

way of the shunt without traversing the pulmonary circuit.

Benenson and Hitzig, who employed saccharin, obtained similar abbreviations of the arm-to-tongue time. They realized, however, that a decreased circulation time, although suggestive of right-to-left shunt, is not necessarily diagnostic. Marked anemia or severe thyrotoxicosis may cause a similar abbreviation of the circulation time.

Circulation time was also studied by means of ether (Benenson and Hitzig); this volatile substance sets off cutaneous paresthesias in the systemic circuit which are pathognomonic for a right-to-left shunt.

When 3 to 5 minims of ether is diluted with 10 minims of normal saline and injected, as in tests for determining circulation time, the ether produces unpleasant paresthesias of the skin of the face and subsequently of the extremities, because of the entrance of this substance into the systemic arterial circulation. Ordinarily, when ether is injected, it volatilizes and escapes almost completely from the lung during the first circuit of the blood. Only a negligible amount may remain and eventually reach the systemic arterial capillaries, and if so, it never causes any paresthetic phenomena. However, in the presence of a venoarterial communication, ether in variable amounts is shunted into the left side of the heart from where this gas (ether boils at body temperature) is propelled into the systemic circuit,

## 6-84 CONGENITAL HEART DISEASE

The curves obtained varied with the site of the defect. In the absence of any left-to-right shunt, rapid injection of an indicator into the left atrium, left ventricle, or thoracic aorta yielded a primary curve with a sharp rapid ascent and a slightly slower descent. An injection proximal to the ventricular defect shunted off some of the dye through the pulmonary

circulation and caused an abrupt decline in rate of fall in concentration. An injection distal to the site of shunt gave a normal curve. Thus selective injection of indicator into various sites would lead to dilution curves characteristic of the location of the defect and thereby to more precise localization of the left-to-right shunt.

lar or oral mucosa represents the right ventricle-to-face circulation time

With this method, a right ventricle-to-face circulation time of 4 sec or less is the average limit between the presence or absence of an interventricular right-to-left shunt. Readings above 4 sec tend to indicate that the shunt is at the atrial rather than at the ventricular level. The presence or absence of a ventricular right-to-left shunt may, therefore, be determined by the right ventricle-to-face circulation time, there being an early end point in the latter. In the absence of a ventricular shunt, the degree of prolongation of the right ventricle-to-face time may serve as a possible index to the degree of severity of the pulmonary stenosis

EVANS BLUE (T 1824) (RIGHT VENTRICLE-TO-EAR TIME). Lasser et al employed Evans blue in the determination of the circulation time from the right ventricle to the ear. When the earpiece of a Millikan oximeter was attached to the patient's ear, 5 ml (3 ml in children) of 0.5 per cent aqueous solution of Evans blue (T 1824) was rapidly injected through the cardiac catheter situated in the right ventricle below the tricuspid orifice. The time elapsing between the beginning of the injection (catheter time 0.75 to 1 sec) and the initial deflection of the oximeter galvanometer represented the circulation time from the right ventricle to the ear. As the arterial concentration necessary to cause the initial deflection is not known, the values obtained do not really represent the true minimum circulation time, but only the apparent minimum dye appearance time, which varies with the sensitivity and speed of response of the oximeter, and are consequently not comparable with other techniques. The average circulation time in cases with a ventricular septal defect was 4 sec (with a range of 3.5 to 4.7 sec). The average of the second group was 7.4 sec (with a range of 5.3 to 10 sec). It was concluded that a circulation time from the right ventricle to the ear of less than 5 sec is strong evidence of the presence of a right-to-left shunt through an overriding aorta. By this means, such a shunt could be differentiated from that of an atrial septal defect plus pulmonary stenosis. Indigo carmine may be substituted for Evans blue in the performance of this diagnostic

test for the localization of interventricular shunt.

**Subjective Method for Diagnosis of Right-to-left Shunt.** ETHER METHOD FACIAL PARESTHESIAS OR (RIGHT VENTRICLE-TO-FACIAL-PARESTHESIA TIME). As far as the author knows, this method has not been tried in cardiac catheterization. There appears to be unjustifiable fear associated with the intracardiac injection of ether. In the author's judgment, injection of minute amounts of ether carries with it no significant risk. The appearance of paresthesias following such an injection would help to differentiate promptly between an interatrial and an interventricular septal defect with pulmonary stenosis. For this purpose, the author recommends the injection of 2 to 3 minims ether mixed with 3 to 5 ml saline. This could be rapidly injected into the heart after the catheter has been placed below the tricuspid orifice. Although the mere appearance of paresthesias would serve as the diagnostic indicator for the presence of a right-to-left shunt at the ventricular level, the time elapsing between the injection and the onset of facial paresthesias could also be measured.

The ether method could therefore be employed as a qualitative and quantitative test during cardiac catheterization for the diagnosis of a ventricular defect with an overriding aorta, conversely, the absence of a right-to-left shunt below the tricuspid orifice. Based on a long experience with the conventional ether method, the author believes that the values obtained should compare well with those obtained with fluorescein, Evans blue, or indigo carmine.

**Objective Method for Diagnosis of Left-to-right Shunts.** Braunwald et al. employed a technique which makes possible the precise localization of left-to-right shunts. A dye indicator, Evans blue or indigo carmine, was rapidly injected into chambers of the left heart or aorta via left heart catheterization. When the dye indicator was rapidly injected and the dilution curve was recorded from a peripheral artery (femoral or ulnar) by means of a cuvette densitometer, a characteristic dye dilution curve was obtained (Part 4, Chap 6). Through this technique, differentiation could be made between (1) ventricular septal defect and aortic septal defect, (2) aortic septal defect and patent ductus arteriosus.

In other congenital heart diseases associated with enlargement of both atria, the tall P waves become also broad (0.12 sec or more in lead II) and diphasic, with a predominant negative phase in  $V_1$  to  $V_2$ . These signs of bilateral enlargement are found in (1) atrial septal defect, (2) AV communis, (3) tricuspid atresia

In tricuspid atresia, the broad and diphasic P wave has the peculiarity that in several leads, the first phase (due to the electrical forces of the right atrium) is greater than the second (due to the electrical forces of the left atrium).

**P-R Interval.** Lengthening of the P-R interval above 0.20 sec in lead II (first-degree AV block) is observed in (1) atrial septal defect, (2) ventricular septal defect, (3) Ebstein's disease, (4) patent ductus arteriosus. Second and third (complete) degree of AV block may also be present in congenital heart disease. Complete AV block is not necessarily associated with ventricular septal defect, as erroneously believed in the past.

**QRS Complex and T Wave.** The determination of the mean manifest electrical axes of the QRS complex and the T wave (AQRS and

# The electrocardiogram in congenital heart disease

DEMETRIO SODI PALLARES  
AND MARIO R. TESTELLI

Many treatises of congenital heart disease and textbooks of electrocardiography do not sufficiently stress that *the electrocardiogram is an important aid for the diagnosis of congenital heart disease*. In the authors' opinion, when the electrocardiogram is "understood" in relation to the activation process, certain "patterns" acquire a significance that is specific for certain groups of congenital malformations of the heart or even for individual entities. Specifically, through the electrocardiographic diagnosis of enlargement (hypertrophy or dilatation) of one or more cardiac chambers and of myocardial damage (ischemia or injury), hemodynamic alterations can be recognized with a good degree of accuracy. Once these alterations are recognized, the main diagnostic possibilities can be suggested.

## GENERAL APPROACH TO ELECTROCARDIOGRAPHY

Before giving a description of the more frequent "patterns" that are encountered in the various forms of congenital heart disease, the approach to electrocardiography in congenital heart disease that is followed at the National Institute of Cardiology of Mexico will be briefly outlined (Sodi Pallares).

**P Wave.** In some congenital heart diseases, characteristic alterations of the P wave (the "P congenitale" of Zuckermann et al) are observed, peaked and tall P waves (3 mm or more), which are usually of normal duration in leads I, II, aVF, and aVL; the AP is around

+30°. In the right precordial leads ( $V_1$  to  $V_2$ ), the P wave is positive or sharply diphasic with a predominantly positive phase.

The P congenitale is frequently found in the following conditions. (1) isolated or pure pulmonary stenosis (trilogy, tetralogy, pentalogy), (2) "complicated" pulmonary stenosis, (3) transposition of the great vessels, (4) common trunk, (5) AV communis (total or partial), (6) Ebstein's disease, (7) tricuspid stenosis (congenital or acquired).

In Ebstein's disease and tricuspid stenosis, a special type of P congenitale is encountered: the voltage of the P wave can be greater than that of the QRS complex in  $V_1$  to  $V_2$  (giant P wave).

Although the degree of cyanosis may be important, the P congenitale is thought to be due to enlargement of the right atrium in hearts with horizontal electrical position. It is worth pointing out the great similarity in pattern between the P congenitale and the "P pulmonale" that is typically found in chronic cor pulmonale. The only difference is that the AP of the P pulmonale is located around +80° (P wave tall and peaked in leads II, III, and aVF) as a result of increased electrical forces of the enlarged right atrium in hearts with vertical electrical position. The similarity between the P congenitale and the P pulmonale is, then, easily understood, since both are fundamentally due to the same mechanism (right atrial enlargement), the latter when the heart is vertical, the former when the heart is horizontal.

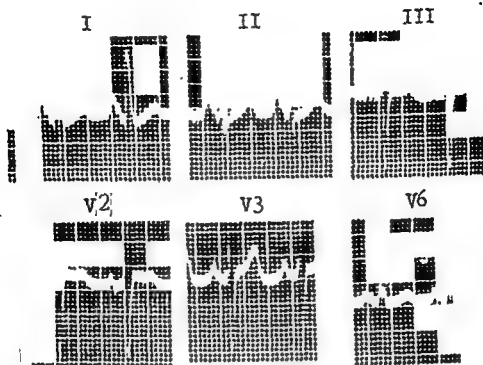

Fig. 6-20. Electrocardiogram of a patient with tricuspid atresia. (This and all subsequent electrocardiograms were taken with normal standardization for the limb leads and with N/2 standardization for the precordial leads.) (Courtesy of the American Heart Journal.)

tions are not included). Like any other table that might be suggested, it is a simple and intended to orient the clinician. The next and necessary step is to study the entire electrocardiogram in function of the activation process (see Part 2, Chap. 37, Epicardial and Endocardial Electrocardiograms).

### PATTERNS OF CONGENITAL HEART DISEASE IN THE CHEST LEADS

In order to facilitate the understanding of the electrocardiogram in the various congenital heart diseases, a brief review of the most important unipolar QRS patterns recorded by the precordial leads will be made.

**Tall R Wave in  $V_1$  to  $V_2$ .** The normal pattern in  $V_1$  to  $V_2$  is rS with negative T wave up to about 15 years of age. The R wave in  $V_1$  to  $V_2$  is considered tall when the ratio R/S or R/q is greater than 1 or when the ratio R/R + S is greater than 0.5. The electrocardiograms of children under the age of 3 years should be excluded because ratios greater than 1 or 0.5, respectively, frequently correspond to hearts that are clinically and radiologically normal.

A tall R wave in  $V_1$  to  $V_2$  can be found with ventricular complexes of the following types: R wave with or without initial slurring, Rs, qR,

qRs, or rR (Fig. 6-21A). This pattern in  $V_1$  to  $V_2$  is characteristic of right ventricular hypertrophy (anatomic diagnosis) and right ventricular systolic overload (hemodynamic correlation).<sup>1</sup> The pattern is encountered in 10 congenital and, less frequently, in 3 acquired heart diseases.

- 1 Isolated pulmonary stenosis
- 2 "Complicated" pulmonary stenosis (trilogy, tetralogy, or pentalogy)
- 3 Idiopathic or essential pulmonary hypertension
- 4 Patent ductus arteriosus
- 5 Ventricular septal defect
- 6 Atrial septal defect
- 7 Eisenmenger complex
- 8 AV communis (total or partial)
- 9 Common trunk
10. Transposition of the great vessels
  - a Mitral valve disease (stenosis, insufficiency, or both)
  - b Chronic cor pulmonale

<sup>1</sup> Ventricular systolic overload, according to Cabrera and Monroy (1952a and b), is the result of an increase of the mean systolic pressure within the ventricle, which may or may not be associated with hypertension in the corresponding artery (aorta for the left ventricle, and pulmonary artery for the right ventricle).

AT) in the frontal and horizontal planes has proved to be useful for the diagnosis of uncomplicated congenital heart diseases (Ayala y De Landero et al.). Figure 6-18 represents an extension of Bayley's triaxial system to which a four-quadrant system for the horizontal plane has been added.

KEY TO SYMBOLS FOR CONGENITAL CARDIAC MALFORMATIONS

| Congenital malformation            | Abbreviations | Abbreviations used in Fig 6-18 |
|------------------------------------|---------------|--------------------------------|
| Aortic stenosis                    | AS            | a                              |
| Atrial septal defect               | ASD           | A                              |
| Atroventricular communis           | AVC           | v                              |
| Coarctation of the aorta           | Co Ao.        | c                              |
| Common trunk                       | C.T           | C                              |
| Ebstein's disease                  | Ebst          | E                              |
| Eisenmenger's complex              | IES           | e                              |
| Patent ductus arteriosus           | PDA           | D                              |
| Pentology of Fallot                | Penta         | p                              |
| Pure pulmonary stenosis            | PPS           | P                              |
| Single ventricle                   | SV            | S                              |
| Tetralogy of Fallot                | Tetra         | T                              |
| Transposition of the great vessels | TGV           | G                              |
| Tricuspid atresia                  | TA            | At                             |
| Trilogy of Fallot                  | Tri           | t                              |
| Ventricular septal defect          | VSD           | V                              |

Fig. 6-19. The four quadrants in the horizontal plane (seen from above) determined by the positive (+) and negative (-) areas of the QRS complex and T wave in leads  $V_2$  and  $V_6$ . (Courtesy of the American Heart Journal)

the symbols corresponding to the congenital heart diseases which present that particular localization of AQRS and AT in the frontal and horizontal planes. The symbols are explained in the annexed table (Ayala y De Landero et al.).

An example will serve to illustrate how to use this method in the study of congenital heart disease. In the electrocardiogram of Fig 6-19, the AQRS in the frontal plane is  $-30^\circ$ , i.e., it falls in the first large sextant, and AT is  $+50^\circ$ , which falls in the sixth small sextant (comprised in the first large sextant). Next, the horizontal AQRS and AT are considered. According to the scheme of Fig 6-18, the AQRS in the horizontal plane (AQRS-H) is localized in the first large quadrant and the AT in the fourth smaller AT-H quadrant. In summary, the electrocardiogram under study (Fig. 6-19) is localized as follows: AQRS-F (first large sextant), AT-F (sixth small sextant), AQRS-H (first large quadrant), and AT-H (fourth small quadrant).

symbol  
sociates  
and AT  
tion of the aorta C, atrial septal defect A, ventricular septal defect V, aortic stenosis a, and AV communis c. In the electrocardiogram under discussion, the diagnosis proved to be tricuspid atresia

The table shown with Fig. 6-18 helps to orient the diagnosis toward the most common possibilities in the field of congenital heart disease (complex anomalies and rare malforma-

The use of the table may be summarized as follows:

1 The large triaxial system (AQRS-F) divides the frontal planes in six large sextants (AT-F). The first stage then consists of localizing the AQRS in one of the six large sextants.

2 Within each large sextant there is a smaller triaxial system emanating from the black AT-F, which serves to localize the AT in the frontal plane.

3 Within each of the 36 frontal AT sextants are four large quadrants emanating from a white circle labeled AQRS-H, which are used for the determination of AQRS in the horizontal plane according to the scheme of Fig 6-18.

4 Within each of the 144 horizontal QRS quadrants are four smaller quadrants emanating from white circles, labeled AT-H, which serve to localize the AT in the horizontal plane according to the same scheme of Fig 6-19.

Once these four steps are followed, any electrocardiogram can be quickly localized in any of the 576 small quadrants of Fig. 6-18. Within these quadrants are inscribed, in order of frequency,

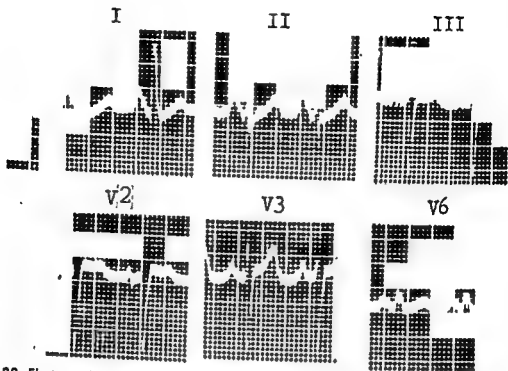

Fig 6-20. Electrocardiogram of a patient with tricuspid atresia. (This and all subsequent electrocardiograms were taken with normal standardization for the limb leads and with N/2 standardization for the precordial leads) (Courtesy of the American Heart Journal.)

tions are not included). Like any other table that might be suggested, it is a simple and intended to orient the clinician. The next and necessary step is to study the entire electrocardiogram in function of the activation process (see Part 2, Chap 37, Epicardial and Endocardial Electrocardiograms).

#### PATTERNS OF CONGENITAL HEART DISEASE IN THE CHEST LEADS

In order to facilitate the understanding of the electrocardiogram in the various congenital heart diseases, a brief review of the most important unipolar QRS patterns recorded by the precordial leads will be made.

**Tall R Wave in  $V_1$  to  $V_2$ .** The normal pattern in  $V_1$  to  $V_2$  is rS with negative T wave up to about 15 years of age. The R wave in  $V_1$  to  $V_2$  is considered tall when the ratio R/S or R/q is greater than 1 or when the ratio R/R + S is greater than 0.5. The electrocardiograms of children under the age of 3 years should be excluded because ratios greater than 1 or 0.5, respectively, frequently correspond to hearts that are clinically and radiologically normal.

A tall R wave in  $V_1$  to  $V_2$  can be found with ventricular complexes of the following types. R wave with or without initial slurring, Rs, qR,

qRs, or rR (Fig 6-21A). This pattern in  $V_1$  to  $V_2$  is characteristic of *right ventricular hypertrophy* (anatomic diagnosis) and *right ventricular systolic overload* (hemodynamic correlation). The pattern is encountered in 10 congenital and, less frequently, in 3 acquired heart diseases

1. Isolated pulmonary stenosis
2. "Complicated" pulmonary stenosis (tri-ogy, tetralogy, or pentalogy)
3. Idiopathic or essential pulmonary hypertension
4. Patent ductus arteriosus } with marked
5. Ventricular septal defect } pulmonary
6. Atrial septal defect } hypertension
7. Eisenmenger complex
8. AV communis (total or partial)
9. Common trunk
10. Transposition of the great vessels
  - a Mitral valve disease (stenosis, insufficiency, or both)
  - b Chronic cor pulmonale

<sup>1</sup> Ventricular systolic overload, according to Cabrera and Monroy (1952a and b), is the result of an increase of the mean systolic pressure within the ventricle, which may or may not be associated with hypertension in the corresponding artery (aorta for the left ventricle, and pulmonary artery for the right ventricle).

V<sub>1</sub>-V<sub>2</sub>

Fig 6-21A. The pattern of tall R wave in leads V<sub>1</sub> to V<sub>2</sub> (R with or without initial slurring, Rs, qR, qRs, or rR) characteristic of right ventricular hypertrophy, which can be found in 10 congenital and, less frequently, in 3 acquired heart diseases. According to the form of the T wave (positive, diphasic, or negative) in the same leads, three subgroups of congenital heart diseases can be considered (see text).

c. Fibrocystic disease of the pancreas (mucoviscidosis)

It should be said that in correspondence with a tall R wave in V<sub>1</sub> to V<sub>2</sub>, tall, isodiphasic complexes are recorded in the "transitional leads" (V<sub>3</sub> to V<sub>4</sub>). In the opinion of the authors, these complexes should be interpreted as the potential variations of the hypertrophied, low right septal mass. In the absence of left ventricular hypertrophy, rS is also recorded in V<sub>5</sub> to V<sub>6</sub>.

If the form of the T wave in the same leads is considered and the acquired heart diseases are excluded, the diagnostic possibilities are reduced, and three subgroups can be considered:

TALL R WAVE WITH POSITIVE T WAVE IN V<sub>1</sub> TO V<sub>2</sub>. Acyanotic Heart Diseases

1. Ventricular septal defect
2. Isolated pulmonary stenosis
3. Patent ductus arteriosus

Cyanotic Heart Diseases

1. Tetralogy of Fallot
2. Transposition of the great vessels
3. Common trunk

TALL R WAVE WITH DIPHASIC T WAVE IN V<sub>1</sub> TO V<sub>2</sub> (negative T wave with terminal positivity preceded by sagging and upward convexity of the RS-T segment). This pattern can be found in the same two groups above. However, the value of right ventricular or pulmonary artery pressure is comparatively greater for the same disease when the pattern of tall

R wave in V<sub>1</sub> to V<sub>2</sub> is accompanied by a diphasic T wave than when it is accompanied by a positive T wave.<sup>2</sup>

TALL R WAVE WITH NEGATIVE T WAVE IN V<sub>1</sub> TO V<sub>2</sub>. When a tall R wave in the right precordial leads is followed by a negative T wave of the ischemic type (symmetric), the degree of right ventricular hypertrophy (and systolic overload) is extreme. The right ventricular systolic pressure is equal to or higher than the left ventricular systolic pressure, and the disease has reached the final stage of its natural evolution.

In order of frequency, this pattern is seen in (1) isolated pulmonary stenosis, (2) trilogy of Fallot, (3) idiopathic or essential pulmonary hypertension, (4) Eisenmenger complex, (5) patent ductus arteriosus (few cases), (6) atrial septal defect (few cases).

It should be appreciated that the pattern of tall R wave in V<sub>1</sub> to V<sub>2</sub> in congenital heart disease acquires its main diagnostic significance when it is considered in conjunction with the T-wave changes in the same leads. With increasing pressure inside the right ventricle, the

<sup>2</sup> It is evident that any electrocardiographic pattern must be evaluated in relation to the specific congenital heart disease in which it is encountered. Thus the hemodynamic significance of a given pat-

tern is in-  
moderate in pure pulmonary stenosis, moderate in atrial septal defect, and

T wave changes from positive to diphasic, and finally becomes negative. By analogy to what has been found in experimental coronary occlusion and in clinical coronary heart disease, the T-wave changes in congenital heart disease are interpreted to indicate (1) subendocardial ischemia of the free right ventricular wall (positive T wave in  $V_1$  to  $V_2$ ); (2) progressive myocardial ischemia (diphasic T wave in  $V_1$  to  $V_2$ ); (3) subepicardial ischemia (negative T wave in  $V_1$  to  $V_2$ ).

**rs Complex with Positive T Wave in  $V_1$  to  $V_2$ .** It is commonly accepted that a ventricular complex of the rS type (with an r/S ratio greater than 1:10) in the right precordial leads indicates *left ventricular hypertrophy*, the S wave being due to the electrical forces of the hypertrophied left ventricle pointing toward the left and backwards. However, it is not sufficiently known that the same pattern may be observed in cases of *right ventricular hypertrophy*, more precisely of hypertrophy of the basal portions (*crista supraventricularis*) of the right ventricle. In such cases, the rS complex with positive T wave in  $V_1$  to  $V_2$  represents the potential variations transmitted from the trabecular zone of the right ventricle. When it is doubtful whether the rS complex in  $V_1$  to  $V_2$  indicates left or right ventricular hypertrophy, the differential diagnosis can be made by considering the pattern of lead aVR: in right ventricular hypertrophy, there is a qR shape with late and tall R wave; in left ventricular hypertrophy, there is a Qr pattern.

**rs Complex with Positive T Wave in  $V_1$  to  $V_2$ —Indicative of Right Ventricular Hypertrophy (RVH).** This is found in (1) tetralogy of Fallot,<sup>3</sup> (2) transposition of the great vessels.

**rs Complex with Positive T Wave in  $V_1$  to  $V_2$ —Indicative of Left Ventricular Hypertrophy (LVH).** This is found in (1) tricuspid atresia, (2) aortic or subaortic stenosis, (3) coarctation of the aorta.

**rsR' Complex in  $V_1$  to  $V_2$ .** Certain electrocardiograms show a tall and late R wave (complexes of the rsR' or rsRS' type) in the right precordial leads while qRS complexes with slurred S wave are observed in the left pre-

cordial leads (Fig. 6-21B, A). Studies of "direct" electrocardiography in dog and man have demonstrated that in uncomplicated right bundle branch block (RBBB), the patterns recorded in  $V_1$  to  $V_2$  are due to transmission of the potential variations of the free right ventricular wall, those of  $V_3$  are due to the trabecular zone of the right ventricle, those of  $V_4$  are due to the right septal mass, and those of  $V_5$  to  $V_6$  are due to the free left ventricular wall. On the basis of these observations, a diagnosis of right ventricular enlargement (dilatation or hypertrophy) is made when right ventricular patterns are recorded up to  $V_5$  to  $V_6$  (Fig. 6-21B, B). When the pattern of the right atrium (in the absence of myocardial infarction) is recorded in  $V_1$  to  $V_2$  and a right ventricular pattern is recorded in the other precordial leads (Fig. 6-21B, C), *right ventricular and right atrial enlargement* is diagnosed. If the pattern of the right atrium is recorded in several precordial leads (Fig. 6-21B, D), a *giant right atrium* is present. When increased voltage of the positive deflections (with the pattern of RBBB) is recorded in  $V_3$  and  $V_4$ , hypertrophy of the right septal mass and (by deduction) of the entire right ventricle is diagnosed (Fig. 6-21B, E). Following the same line of reasoning, it is not surprising that *left ventricular hypertrophy* can be diagnosed in the presence of RBBB when left ventricular patterns are recorded from  $V_3$  to  $V_6$  (Fig. 6-21B, F). In the same way, *left ventricular hypertrophy and right atrial enlargement* are diagnosed when, in addition to the fact that left ventricular patterns are already recorded in  $V_3$ , the pattern of the right atrium is recorded in leads  $V_1$  to  $V_2$  (Fig. 6-21B, G).

The pattern of RBBB with characteristic variations (see below) is encountered in the following diseases. (1) atrial septal defect, (2) ventricular septal defect, (3) AV communis (with AQRS deviated to the left), (4) ostium primum (with AQRS deviated to the left), (5) Eisenmenger complex, (6) Ebstein's disease.

**QS Pattern with Positive T Wave in  $V_1$  to  $V_2$ .** In the absence of myocardial infarction, a QS pattern with positive T wave in  $V_1$  to  $V_2$  is indicative of *left bundle branch block* (usually accompanied by LVH and systolic overload) and is associated with characteristic patterns in leads  $V_3$  to  $V_6$ . Depending on the degree of the LBBB, the left precordial leads may show

<sup>3</sup> It should not cause surprise that the electrocardiogram in the tetralogy of Fallot may present a tall R wave or an rS complex with positive T wave in  $V_1$  to  $V_2$ . This depends on the degree and location of the hypertrophy of the right ventricle.

$V_1-V_2$ 

Fig 6-21A. The pattern of tall R wave in leads  $V_1$  to  $V_2$  (R with or without initial slurring, R<sub>s</sub>, qR, qR<sub>s</sub>, or rR) characteristic of right ventricular hypertrophy, which can be found in 10 congenital and, less frequently, in 3 acquired heart diseases. According to the form of the T wave (positive, diphasic, or negative) in the same leads, three subgroups of congenital heart diseases can be considered (see text)

c. Fibrocystic disease of the pancreas (mucoviscidosis)

It should be said that in correspondence with a tall R wave in  $V_1$  to  $V_2$ , tall, isodiphasic complexes are recorded in the "transitional leads" ( $V_3$  to  $V_4$ ). In the opinion of the authors, these complexes should be interpreted as the potential variations of the hypertrophied, low right septal mass. In the absence of left ventricular hypertrophy, rS is also recorded in  $V_3$  to  $V_6$ .

If the form of the T wave in the same leads is considered and the acquired heart diseases are excluded, the diagnostic possibilities are reduced, and three subgroups can be considered.

TALL R WAVE WITH POSITIVE T WAVE IN  $V_1$  TO  $V_2$  Cyanotic Heart Diseases

1. Ventricular septal defect
  2. Isolated pulmonary stenosis
  3. Patent ductus arteriosus
- Cyanotic Heart Diseases
1. Tetralogy of Fallot
  2. Transposition of the great vessels
  3. Common trunk

TALL R WAVE WITH DIPHASIC T WAVE IN  $V_1$  TO  $V_2$  (negative T wave with terminal positivity preceded by sagging and upward convexity of the RS-T segment). This pattern can be found in the same two groups above. However, the value of right ventricular or pulmonary artery pressure is comparatively greater for the same disease when the pattern of tall

R wave in  $V_1$  to  $V_2$  is accompanied by a diphasic T wave than when it is accompanied by a positive T wave.<sup>2</sup>

TALL R WAVE WITH NEGATIVE T WAVE IN  $V_1$  TO  $V_2$  When a tall R wave in the right precordial leads is followed by a negative T wave of the ischemic type (symmetric), the degree of right ventricular hypertrophy (and systolic overload) is extreme. The right ventricular systolic pressure is equal to or higher than the left ventricular systolic pressure, and the disease has reached the final stage of its natural evolution.

In order of frequency, this pattern is seen in (1) isolated pulmonary stenosis, (2) triad of Fallot, (3) idiopathic or essential pulmonary hypertension, (4) Eisenmenger complex, (5) patent ductus arteriosus (few cases), (6) atrial septal defect (few cases).

It should be appreciated that the pattern of tall R wave in  $V_1$  to  $V_2$  in congenital heart disease acquires its main diagnostic significance when it is considered in conjunction with the T-wave changes in the same leads. With increasing pressure inside the right ventricle, the

<sup>2</sup> It is evident that any electrocardiographic pattern must be evaluated in relation to the specific congenital heart disease in which it is encountered. Thus the hemodynamic significance of a given pattern may vary according to the circumstances. This is also true of certain hemodynamic data. For instance, a right ventricular pressure of 80 mm Hg is considered very high in atrial septal defect, and moderate in pure pulmonary stenosis.

T wave changes from positive to diphaseic, and finally becomes negative. By analogy to what has been found in experimental coronary occlusion and in clinical coronary heart disease, the T-wave changes in congenital heart disease are interpreted to indicate (1) subendocardial ischemia of the free right ventricular wall (positive T wave in  $V_1$  to  $V_2$ ), (2) progressive myocardial ischemia (diphaseic T wave in  $V_1$  to  $V_2$ ); (3) subepicardial ischemia (negative T wave in  $V_1$  to  $V_2$ ).

**rS Complex with Positive T Wave in  $V_1$  to  $V_2$ .** It is commonly accepted that a ventricular complex of the rS type (with an r/S ratio greater than 1:10) in the right precordial leads indicates *left ventricular hypertrophy*, the S wave being due to the electrical forces of the hypertrophied left ventricle pointing toward the left and backwards. However, it is not sufficiently known that the same pattern may be observed in cases of *right ventricular hypertrophy*, more precisely of hypertrophy of the basal portions (*crista supraventricularis*) of the right ventricle. In such cases, the rS complex with positive T wave in  $V_1$  to  $V_2$  represents the potential variations transmitted from the trabecular zone of the right ventricle. When it is doubtful whether the rS complex in  $V_1$  to  $V_2$  indicates left or right ventricular hypertrophy, the differential diagnosis can be made by considering the pattern of lead aVR. In right ventricular hypertrophy, there is a qR shape with late and tall R wave, in left ventricular hypertrophy, there is a Qr pattern.

**rS Complex with Positive T Wave in  $V_1$  to  $V_2$ —Indicative of Right Ventricular Hypertrophy (RVH).** This is found in (1) tetralogy of Fallot,<sup>3</sup> (2) transposition of the great vessels.

**rS Complex with Positive T Wave in  $V_1$  to  $V_2$ —Indicative of Left Ventricular Hypertrophy (LVH).** This is found in (1) tricuspid atresia, (2) aortic or subaortic stenosis, (3) coarctation of the aorta

**rsR' Complex in  $V_1$  to  $V_2$ .** Certain electrocardiograms show a tall and late R wave (complexes of the rsR' or rsR'S' type) in the right precordial leads while qRS complexes with slurred S wave are observed in the left pre-

cordial leads (Fig. 6-21B, A). Studies of "direct" electrocardiography in dog and man have demonstrated that in uncomplicated right bundle branch block (RBBB), the patterns recorded in  $V_1$  to  $V_2$  are due to transmission of the potential variations of the free right ventricular wall, those of  $V_3$  are due to the trabecular zone of the right ventricle, those of  $V_4$  are due to the right septal mass, and those of  $V_5$  to  $V_6$  are due to the free left ventricular wall. On the basis of these observations, a diagnosis of right ventricular enlargement (dilatation or hypertrophy) is made when right ventricular patterns are recorded up to  $V_5$  to  $V_6$  (Fig. 6-21B, B). When the pattern of the right atrium (in the absence of myocardial infarction) is recorded in  $V_1$  to  $V_2$  and a right ventricular pattern is recorded in the other precordial leads (Fig. 6-21B, C), *right ventricular and right atrial enlargement* is diagnosed. If the pattern of the right atrium is recorded in several precordial leads (Fig. 6-21B, D), a *giant right atrium* is present. When increased voltage of the positive deflections (with the pattern of RBBB) is recorded in  $V_3$  and  $V_4$ , hypertrophy of the right septal mass and (by deduction) of the entire right ventricle is diagnosed (Fig. 6-21B, E). Following the same line of reasoning, it is not surprising that *left ventricular hypertrophy* can be diagnosed in the presence of RBBB when left ventricular patterns are recorded from  $V_1$  to  $V_6$  (Fig. 6-21B, F). In the same way, *left ventricular hypertrophy and right atrial enlargement* are diagnosed when, in addition to the fact that left ventricular patterns are already recorded in  $V_4$ , the pattern of the right atrium is recorded in leads  $V_1$  to  $V_2$  (Fig. 6-21B, G).

The pattern of RBBB with characteristic variations (see below) is encountered in the following diseases (1) atrial septal defect, (2) ventricular septal defect, (3) AV communis (with AQRS deviated to the left), (4) ostium primum (with AQRS deviated to the left), (5) Eisenmenger complex, (6) Ebstein's disease

**QS Pattern with Positive T Wave in  $V_1$  to  $V_2$ .** In the absence of myocardial infarction, a QS pattern with positive T wave in  $V_1$  to  $V_2$  is indicative of *left bundle branch block* (usually accompanied by LVH and systolic overload) and is associated with characteristic patterns in leads  $V_5$  to  $V_6$ . Depending on the degree of the LBBB, the left precordial leads may show

<sup>3</sup> It should not cause surprise that the electrocardiogram in the tetralogy of Fallot may present a tall R wave or an rS complex with positive T wave in  $V_1$  to  $V_2$ . This depends on the degree and location of the hypertrophy of the right ventricle

Fig 6-21B. Patterns of ventricular and/or atrial enlargements (dilatation or hypertrophy) in the presence of RBBB. A. Uncomplicated RBBB. B. RBBB with right ventricular enlargement. C. RBBB with right ventricular and right atrial enlargement. D. RBBB with giant right atrium. E. RBBB with right ventricular hypertrophy (right septal mass). F. RBBB with left ventricular hypertrophy. G. RBBB with left ventricular hypertrophy and right atrial enlargement.

Fig. 6-22. Ventricular septal defect In  $V_1$  the morphology is "M"-shaped, with the first positivity (R) greater than the second (R'). The deep Q wave in  $V_3$  and the tall R wave in  $V_1$  are interpreted to indicate left septal hypertrophy.

only absence of the normal q wave (first degree), an initial slurring of the R wave with or without rounded peak (second degree), or an M pattern (third, or advanced, degree).

The patterns of LBBB are found in (1) aortic stenosis, (2) tricuspid atresia, (3) coarctation of the aorta, (4) patent ductus arteriosus

1. *Acyanotic heart diseases*
  - a. Patent ductus arteriosus
  - b. Ventricular septal defect
2. *Cyanotic heart diseases*
  - a. Patent of Fallot
  - b. Tricuspid atresia
  - c. Common trunk
  - d. AV communis

**Tall R Wave in  $V_1$  to  $V_2$  and in  $V_5$  to  $V_6$ .** Under this heading are included the electrocardiograms showing "true" biventricular hypertrophy. As a tall R wave in  $V_5$  to  $V_6$  not too infrequently can correspond to the potential variations of the hypertrophied and dilated right cardiac chambers, one should be certain that the tall R wave in  $V_5$  to  $V_6$  represents the transmission of the potential variations of the associated hypertrophied left ventricle. To this purpose, one should pay attention to three data that confirm the presence of associated hypertrophy: (1) initial q wave in  $V_5$  to  $V_6$ , (2) delayed intrinsicoid deflection in  $V_1$  to  $V_6$ , (3) the transitional complexes of  $V_3$  to  $V_4$  are followed by complexes of the qR type (not rS) in  $V_5$  to  $V_6$ .

The pattern of biventricular hypertrophy frequently corresponds to a systolic overload of the right ventricle associated with a diastolic overload of the left (tall, positive T wave in  $V_5$  to  $V_6$ , in addition to the tall R wave in the same leads). This pattern is usually seen in

\*The term "ventricular diastolic overload," according to Cabrera and Monroy (1952a and b), means that one ventricle receives (in diastole) and ejects (in systole) a greater volume of blood than the other ventricle.

After this outline of the authors' approach to electrocardiography in congenital heart disease, the most representative patterns of the main malformations will be reviewed.

## ELECTROCARDIOGRAPHIC PATTERNS OF THE MOST IMPORTANT MALFORMATIONS

### Ventricular Septal Defect

1. *Signs of RVH with some degree of RBBB.*
  - a In  $V_1$  to  $V_2$ , the first R wave is frequently greater than the second (R') and the T wave is frequently positive (Fig 6-22).
  - b  $V_1$  to  $V_4$  show large isodiphasic complexes with positive T waves [Fig 6-22(1)].
2. *Signs of LVH.*
  - a In  $V_5$  to  $V_6$ , tall R complexes (of the type qRs or qRS) are present, followed by positive and tall (symmetric) T waves. This pattern of LVH is usually accompanied by diastolic overload of the left ventricle with a relatively low right ventricular pressure (not exceeding 60 mm Hg) [Fig. 6-22(1)].
  - b. In  $V_5$  to  $V_6$ , deep and rapid Q waves

Fig. 6-218. Patterns of ventricular and/or atrial enlargements (dilatation or hypertrophy) in the presence of RBBB. A. Uncomplicated RBBB. B. RBBB with right ventricular enlargement. C. RBBB with right ventricular and right atrial enlargement. D. RBBB with giant right atrium. E. RBBB with right ventricular hypertrophy (right septal mass). F. RBBB with left ventricular hypertrophy. G. RBBB with left ventricular hypertrophy and right atrial enlargement.

Fig. 6-22(2). Patent ductus arteriosus without pulmonary hypertension. Tall R waves with an upward concavity of the RS-T segment, and positive and peaked T waves are inscribed from  $V_1$  through  $V_6$ .

### Pure Pulmonary Stenosis

Pure pulmonary stenosis is another malformation in which the electrocardiogram closely correlates with the hemodynamic alterations

1. *Mild degree of stenosis* The electrocardiogram [Fig. 6-22(5)] may be of the type S1-S2-S3 with small isodiphasic complexes in the precordial leads and "normal" R/S or R/S + R ratios in  $V_1$ , and minor changes of the P waves (slightly peaked in lead I and  $V_1$  with AP deviated to the left).

2. *Severe degree of stenosis.* The electrocardiogram becomes more characteristic of RVH [Fig. 6-22(6)]. The T waves in the right precordial leads are usually positive when the right ventricular systolic pressure is lower than the systemic. However, when that pressure is equal to or higher than the systemic, the T waves in the right and then in most precordial leads become negative of the "ischemic type". As discussed earlier, such a pattern is indicative of "extreme" RVH (and systolic overload), a pattern which is more typical of the trilogy of Fallot [Fig. 6-22(13)]

### Eisenmenger Complex

#### 1. Signs of RVH with RBBB.

a. The pattern of the right ventricle (rsR' or rsR'S') is recorded in various precordial leads [Fig. 6-22(7)].

b. Large isodiphasic complexes are seen in the intermediate precordial leads (as in ventricular septal defect); the pattern of the right septal mass (RS) is recorded in  $V_5$  to  $V_6$ .

2. *Signs of hypertrophy of the left septal mass and (by deduction) of the left ventricle.*  
a. Deep and rapid Q wave (less than 0.04 sec) is recorded in leads, reflecting the potential variations of the left ventricle (as in ventricular septal defect).

### Tricuspid Atresia

1. The P wave in the standard leads is tall, broad, and notched, the first peak being greater than the second (Fig. 6-20). In the right precordial leads, the P wave is diphasic, with an important positive phase.

#### 2. Signs of LVH with LBBB.

a. AQRS deviated to the left. It is classically admitted that the association of left axis deviation with cyanosis is highly suggestive of tricuspid atresia.

b. There is an rS complex in  $V_1$  to  $V_2$  and a tall R wave is present in  $V_5$  to  $V_6$  AV Communis (Total or Partial)

1. Evidence of biventricular hypertrophy with RBBB and left axis deviation [Fig. 6-22(8)].

a. Tall R' in  $V_1$  to  $V_2$  (hypertrophy of the

(less than 0.04 sec) are present, synchronous with the first tall R wave in  $V_1$  to  $V_2$ . This fact should be interpreted as evidence of hypertrophy of the interventricular septum, where ventricular activation normally starts (middle third of the left septal mass) (Fig. 6-22).

3 The same patterns of  $V_3$  to  $V_6$  are often recorded also in leads II, III, and aVF.

#### Patent Ductus Arteriosus

1. The P wave may be broad and slurred, with a duration of 0.12 sec or more in the standard leads

2. There is evidence of RVH with systolic overload.

a.  $V_1$  to  $V_2$  present tall R waves with negative T waves

b.  $V_3$  to  $V_6$  show large isodiphasic complexes with positive or diphasic T waves.

3 There is evidence of LVH with diastolic overload

In  $V_5$  to  $V_6$  there are tall R waves with positive T waves. When only these signs are present, the pulmonary pressure is not greatly elevated [Fig. 6-22(2)]. However, when these signs are associated with those of RVH, pulmonary hypertension is present [Fig. 6-22(3)]. Sometimes it is impossible to differentiate the pattern of ventricular septal defect from that of patent ductus arteriosus. It may be of help to remember that the T wave in  $V_1$  to  $V_2$  is frequently positive in ventricular septal defect and diphasic or negative in patent ductus arteriosus.

#### Atrial Septal Defect

1. The P wave in the standard leads is frequently broad (left atrial enlargement). Signs of right atrial enlargement (high and peaked P wave mainly in leads I and II) may also be present.

2. First-degree AV block.

3. Complete or incomplete RBBB [Fig. 6-22(4)].

It is important to know that as the pulmonary hypertension increases, the following modifications are seen:

1. The patterns of leads  $V_3$  to  $V_4$  show an increase in voltage and are "displaced" to the left.

2. The patterns of  $V_1$  to  $V_2$  show more typical evidence of RVH, however, the presence of RBBB is revealed by the initial slurring of the R wave (this is interpreted differently by some authors).

Fig 6-22(1) Ventricular septal defect. Signs of left ventricular hypertrophy with diastolic overloading. Note large isodiphasic complexes in leads  $V_3$  to  $V_6$ .

3 The T waves become more negative and of the "ischemic" type in all leads

In summary, the natural evolution of the electrocardiogram in atrial septal defect\* is toward a pattern of systolic overload of the right ventricle, which is progressively reached.

\* In the natural history of atrial septal defect it is reported that primary pulmonary hypertension is frequently found. This would be in accordance with the electrocardiographic evolution, since the electrocardiogram of atrial septal defect with marked pulmonary hypertension cannot be differentiated from that of primary pulmonary hypertension.

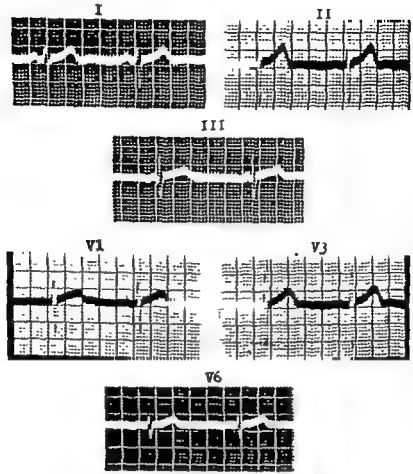

Fig. 6-22(5). Pure pulmonary stenosis. Electrocardiogram of the type  $S_1$ - $S_2$ - $S_3$ .

(less than 0.04 sec) are present, synchronous with the first tall R wave in  $V_1$  to  $V_2$ . This fact should be interpreted as evidence of hypertrophy of the interventricular septum, where ventricular activation normally starts (middle third of the left septal mass) (Fig 6-22).

3. The same patterns of  $V_5$  to  $V_6$  are often recorded also in leads II, III, and aVF.

#### *Patent Ductus Arteriosus*

1. The P wave may be broad and slurred, with a duration of 0.12 sec or more in the standard leads.

2. There is evidence of RVH with systolic overload

a.  $V_1$  to  $V_2$  present tall R waves with negative T waves

b.  $V_3$  to  $V_4$  show large isodiphasic complexes with positive or diphasic T waves

3. There is evidence of LVH with diastolic overload.

In  $V_5$  to  $V_6$  there are tall R waves with positive T waves. When only these signs are present, the pulmonary pressure is not greatly elevated [Fig 6-22(2)]; however, when these signs are associated with those of RVH, pulmonary hypertension is present [Fig 6-22(3)]. Sometimes it is impossible to differentiate the pattern of ventricular septal defect from that of patent ductus arteriosus. It may be of help to remember that the T wave in  $V_1$  to  $V_2$  is frequently positive in ventricular septal defect and diphasic or negative in patent ductus arteriosus.

#### *Atrial Septal Defect*

1. The P wave in the standard leads is frequently broad (*left atrial enlargement*). Signs of *right atrial enlargement* (high and peaked P wave mainly in leads I and II) may also be present

2. *First-degree AV block*

3. *Complete or incomplete RBBB* [Fig 6-22(4)]

It is important to know that as the pulmonary hypertension increases, the following modifications are seen

1. The patterns of leads  $V_3$  to  $V_4$  show an increase in voltage and are "displaced" to the left

2. The patterns of  $V_1$  to  $V_2$  show more typical evidence of RVH; however, the presence of RBBB is revealed by the initial slurring of the R wave (this is interpreted differently by some authors).

Fig. 6-22(1) Ventricular septal defect. Signs of left ventricular hypertrophy with diastolic overloading. Note large isodiphasic complexes in leads  $V_3$  to  $V_4$ .

3. The T waves become more negative and of the "ischemic" type in all leads.

In summary, the natural evolution of the electrocardiogram in atrial septal defect<sup>5</sup> is toward a pattern of systolic overload of the right ventricle, which is progressively reached.

<sup>5</sup> In the natural history of atrial septal defect it is reported that primary pulmonary hypertension is frequently found. This would be in accordance with the electrocardiographic evolution since

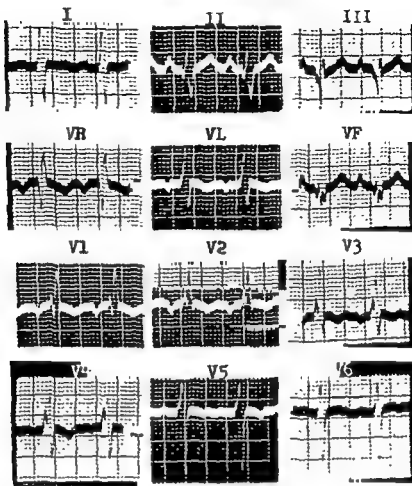

Fig. 6-22(7). Eisenmenger complex. Signs of right ventricular hypertrophy in the presence of RBBB. The deep Q wave in these leads is interpreted to indicate hypertrophy of the left septal wall, as in ventricular septal defect.

free right ventricular wall) and large isodiphasic complexes in  $V_3$  to  $V_4$  (hypertrophy of the right septal mass).

b. Tall R wave in  $V_3$  to  $V_6$  and in other leads (I and aVL), recording the potential variations of the left ventricle (LVH). The increased forces of the hypertrophied left ventricle account for the tall R wave in lead I and the deep S wave in lead III (left axis deviation).

**Osium Primum.** The electrocardiogram in this disease is very similar to that just described for the AV communis (RBBB with  $\Delta$ QRS deviated to the left, plus signs of biventricular hypertrophy), with the difference that the RBBB is of a lesser degree

#### Ebstein's Disease

1 The P wave is of the "congenitale" type or, more characteristically, of the type called "giant"

Fig. 6-22(3) Patent ductus arteriosus with moderate pulmonary hypertension. Signs of biventricular hypertrophy are present, with systolic overloading of the right ventricle and diastolic overloading of the left ventricle

Fig. 6-22(4). Atrial septal defect. There is incomplete RBBB. The unipolar morphologies belonging to the right ventricle and right septal mass are registered from  $V_1$  through  $V_4$ , suggesting right ventricular enlargement.

2 Atrial arrhythmias (fibrillation, flutter, paroxysmal tachycardia) are frequently present.

3 First-degree AV block.

4. Right bundle branch block with right atrial pattern (qR or qRs) recorded in almost all precordial leads [up to  $V_6$  in the example of Fig. 6-22(9)]. These are instances of huge right atrial enlargement (giant right atrium). In other cases, the right atrial pattern is recorded in  $V_1$  to  $V_3$ , and a left ventricular pattern (qRS with data indicating RBBB) is recorded in the other precordial leads. The tracing would then present only right atrial and left ventricular patterns, with absence of the so-called transitional complex. If no RBBB is present, the QR type of complexes with negative T waves (potential variations of the right atrium having normal conduction) may be recorded in several leads, while in the remaining leads the pattern of the left ventricle is observed.

5. Wolff-Parkinson-White syndrome, type B [Fig. 6-22(10)]. When observed in a child, this pattern should always suggest the possibility of Ebstein's disease.

Fig. 6-22(17). Common trunk. There are tall R waves in  $V_1$  and  $V_6$  with complexes of the rS type in  $V_2$  and  $V_3$ .

Fig. 6-22(21). Uncomplicated dextrocardia. "Classic" pattern.

**Tetralogy of Fallot**

1. The P wave is of the congenital type.
2. There is one of the following indications of RVH

- a. Tall R wave in  $V_1$  to  $V_2$  with complexes of the R type with initial slurring, or of the RS or rR types [Fig. 6-22(11)]
- b. Tall R wave in  $V_1$  followed by rS complexes (potential variations of the trabecular zone of the right ventricle) in the other precordial leads [Fig. 6-22(12)]. In these cases, the hypertrophy of the basal portions of the right ventricle (crista supraventricularis) predominates

3. In marked pulmonary stenosis, the pattern resembles that of the trilog of Fallot

**Trilog of Fallot**

1. The P wave is frequently of the congenital type, as in the tetralogy of Fallot

■ There is evidence of "extreme" RVH with systolic overload of the right ventricle [tall R wave with negative T wave in  $V_1$  to  $V_2$ , and frequently up to  $V_4$ , as shown in Fig. 6-22(13)]

3. Elevation of the RS-T segment in leads I and II and less frequently in  $V_5$  to  $V_6$ , as pointed out by Medrano

**Pentology of Fallot.** The pattern is similar to that described for tetralogy of Fallot, with RVH [Fig. 6-22(11)], it differs in that the signs of associated LVH with diastolic overload are more evident [Fig. 6-22(14)].

**Coarctation of the Aorta**

1. Signs of LVH, which become more manifest with progression of the disease: tall R wave in  $V_5$  to  $V_6$  with delayed intrinscoid deflection and deep S wave in the right precordial leads [Fig. 6-22(15)]

2. AQRS is not deviated to the left in three-fourths of the cases

**Congenital Aortic Stenosis**

1. Signs of LVH, as in coarctation of the aorta.

2. Myocardial ischemia is frequently present [Fig. 6-22(16)]

- AQRS is not deviated to the left, as in rule.

**Common Trunk**

1. Signs of **bicentricular hypertrophy** (tall R wave in  $V_1$  to  $V_2$  and in  $V_5$  to  $V_6$ ) while complexes of the rS type (trabecular zone of the right ventricle) are recorded in  $V_2$  to  $V_3$ , as shown in Fig. 6-22(17).

- The T wave is frequently positive in all precordial leads. Patterns of this type need to

Fig. 6-22(20) Single ventricle. Left axis deviation. The complexes are essentially negative in all the precordial leads.

be differentiated from those of the tetralogy and pentology of Fallot.

**Transposition of the Great Vessels, NONCORRECTED TRANSPOSITION.** This is the common variety of transposition, with the aorta arising from the right ventricle

1. Signs of RVH with systolic overload [Fig. 6-22(18)].

2. T waves of the "infantile" type (negative with terminal positivity) have been described in the left precordial leads, accompanied by positive T waves in the right precordial leads (Zuckermann et al.).

**CORRECTED TRANSPOSITION.** This is the less frequent variety of transposition, in which the ventricles are also transposed, for which reason the transposition of the great vessels becomes "corrected." Electrocardiographically, this variety is difficult to diagnose, the typical patterns of the two ventricles cannot be recognized with certainty on account of the transposition and hypertrophy of the right ventricle. The electrocardiograms in this disease are probably the most difficult to interpret; the presence of a

Fig. 6-22(23). Dextrocardia complicated by transposition of the great vessels with the left ventricle on the left side and the right ventricle on the right ("corrected" transposition) 12-lead electrocardiogram (left side of the figure) and thoracic circle (right side). (Courtesy of the American Heart Journal and of Dr. Portillo and coworkers.)

associated RVH. If such complexes are present, the positive QRS complexes in the other precordial leads are due to the hypertrophied right ventricle, and the negative QRS complexes, to the left ventricle [Fig. 6-22(19)]. Negativity of the P wave in lead I speaks for transposition of the atria as well.

**Single Ventricle.** This malformation may be complicated by other abnormalities (transposition of the great vessels, common trunk, Fallot complexes) which greatly influence the electrocardiogram. However, some signs may help: (1) normal P waves, (2) left axis deviation, (3) complexes of the rS or RS type in all precordial leads [Fig. 6-22(20)].

**Dextrocardia, UNCOMPLICATED.** Under this heading are included the cases of so-called "mirror-image" dextrocardia, with no cardiac abnormality but with situs inversus. In these cases, the electrocardiogram presents a well-known, "classic" pattern [Fig. 6-22(21)].

- 1 Negative P wave in leads I and aVL.
- 2 "Mirror image" of the QRS complex in the standard and precordial leads.

It is important to know that in many cases of uncomplicated dextrocardia, there is nodal rhythm. In a normal heart (without dextrocardia), this rhythm is recognized by negative P waves in leads II, III, and aVF and by a positive P wave in aVL, the mean electrical axis of atrial activation (AP) being around  $-60^\circ$  [Fig. 6-22(22)A]. In nodal rhythm with dextrocardia, the P wave is negative in all limb leads except aVR (where it is maximally positive) since the AP becomes oriented toward  $-120^\circ$  [Fig. 6-22(22)B].

**COMPLICATED Dextrocardia** may be complicated by acquired heart diseases, as well as by congenital ones. A detailed description of this condition has been made elsewhere (Portillo et al.), the position of the various cardiac chambers can occasionally be determined with accuracy through a careful study of the electrocardiogram.

The case shown in Fig. 6-22(23) is representative. The negative P wave in leads I and aVL

\* It must be remembered that negativity of the P wave in leads I and aVL is not indicative of absence of cardiac or atrium.

### S.V.C.

### S.V.C.

Fig. 6-22(22) The mean electrical axis of P ( $\bar{A}P$ ) in nodal rhythm. A Normal heart ( $\bar{A}P$  around  $-60^\circ$ ). B Dextrocardia ( $\bar{A}P$  around  $-120^\circ$ ). (Courtesy of the American Heart Journal and of Dr. Portillo and coworkers.)

indicates that dextrocardia is present, the recording of a left ventricular pattern (with signs of LVH) from  $V_2$  to  $V_6$ , and of right ventricular patterns on the right chest [leads at points 9 to 12 of the thoracic circle represented on the right of Fig. 6-22(23)] indicates that the left ventricle is on the left side and the right ventricle on the right. The post-mortem study revealed dextrocardia with situs inversus, transposition of the great vessels, and left ventricular hypertrophy, the left ventricle was on the left side and the right ventricle was on the right ("corrected" transposition of the great vessels).

Fig. 6-23. A Phonocardiogram in ostium secundum type atrial septal defect. Note the irregular low-intensity ejection-type systolic murmur (SM) and widely split 2d sound ( $S_2$ ) at the 2d left intercostal space (2 LIS). B Apical murmur of ostium primum type atrial septal defect. Note the decrescendo systolic murmur (SM), widely split 2d sound ( $S_2$ ), and low-frequency mid-diastolic rumble (DM). C Fourth left intercostal space murmur of same patient with ostium primum type atrial defect. Note the plateau or crescendo shape of systolic murmur (SM), split 2d sound ( $S_2$ ), and middiastolic rumble (DM).

septal defect may best be heard at the lower left sternal border and the apex. It may begin immediately after the 2d sound, or it may have its onset with the 3d sound. Its intensity is usually low, and it is present only in atrial septal defects with a sizable left-to-right shunt and perhaps some cardiac enlargement. The origin of this diastolic rumble is not completely clear, but most likely it is the result of the increased flow across the tricuspid valve.

A high-frequency early *decrescendo* diastolic murmur, characteristic of pulmonary incompetence, may be registered in the relatively rare instances of atrial septal defect associated with pulmonary vascular obstruction.

**Atrial Septal Defect—Ostium Primum Type.** SOUNDS. The only difference in heart sounds between the primum- and secundum-type defect is that the pulmonary closure in the former may be more accentuated, because of the relatively more frequent association of this defect with pulmonary arterial hypertension.

**MURMURS.** The *systolic* murmur is of high intensity and is localized to the lower left sternal border and the apex. Careful registration suggests that the apical murmur resembles the high-frequency *decrescendo* character of *mitral regurgitation* and transmits well out to the posterior axillary line (Fig. 6-23B). This is probably the result of a congenital cleft in the mitral valve which is frequently associated with primum-type atrial defect. The lower left sternal border murmur, by contrast, is similar to the *plateau* shape of the murmur caused by the ventricular septal defect and may originate from the high-velocity flow of blood from left ventricle to right atrium or right ventricle during systole (Fig. 6-23C).

**Ventricular Septal Defect.** SOUNDS. The 1st sound is commonly obscured by the *systolic* murmur at the lower left sternal border. The 2d sound is normally split, the aortic and pulmonary elements are seldom more than 0.04 sec apart. In cases associated with pulmonary hypertension of some degree, the 2d sound is narrowly split, and the pulmonary element is accentuated. An apical 3d sound is noted in most children with sizable left-to-right shunts and cardiac enlargement.

**MURMURS.** A very high-intensity, high-frequency *plateau-shaped* *holosystolic* murmur is registered at the lower left sternal border in

# Phonocardiography in congenital heart disease

ALEXANDER S. NADAS

## INTRODUCTION

The importance of accurate diagnosis in congenital heart disease can scarcely be overstated. Among the tools of diagnosis, the stethoscope has been increasingly emphasized in the past decade. Whereas at first, only the machinery murmur, associated with patent ductus arteriosus, was thought to be pathognomonic for a congenital cardiac deformity, in more recent years, the "stenotic" murmurs of semilunar stenosis, the low-frequency apical diastolic murmurs of the large left-to-right lesions, the characteristic auscultatory phenomena of Ebstein's disease, etc., have been recognized as invaluable landmarks for the clinical identification of individual malformations.

The phonocardiograph serves several purposes in this respect. It is an excellent teaching instrument in that it demonstrates visually what should be perceived at auscultation. Secondly, by means of various reference tracings, it determines the accurate timing of the auscultatory phenomena within the cardiac cycle. Thirdly, by the skillful use of a number of filters, it enables the physician to visualize sound phenomena which lie beyond the reach of the human auditory apparatus. Last, not least, by recording sound phenomena in the same individual through the years, even before and after surgical intervention, an accurate life history of the auscultatory findings may be obtained.

Assuming that the reader is acquainted with

the general principles of phonocardiography,<sup>1</sup> it might be well to discuss the auscultatory phenomena of the commonest individual congenital cardiac malformations.

## THE LEFT-TO-RIGHT SHUNT GROUP

**Atrial Septal Defect—Ostium Secundum Type.** SOUNDS. The 1st sound is of average intensity, sometimes wider than normal. The 2d sound is practically always widely split (more than 0.04 sec), the pulmonary element following the aortic. The splitting, probably the consequence of the increased stroke volume of the right ventricle, does not vary with respiration, in contrast to the normal, where splitting increases considerably on inspiration. The intensity of both semilunar components is average or is only slightly accentuated. A 3d sound is well registered at the apex in most cases.

MURMURS. The systolic murmur of the uncomplicated ostium secundum defect is usually of moderate intensity and rather high frequency and is irregular or diamond-shaped. It begins with the 1st sound and ends usually sometime before the 2d. It is registered best at the 2d left interspace and is present in practically every instance. It is most likely to originate from the right ventricular outflow or the pulmonary artery and probably represents an exaggeration of a physiologic ejection murmur (Fig. 6-23A).

The low-frequency diastolic murmur of atrial

<sup>1</sup> See Part 3, Chap. II Editor

Fig. 6-25. Phonocardiogram of patient with large patent ductus arteriosus and marked pulmonary vascular obstruction with very little shunt. Note the loud 2d sound at the pulmonary area and only faint systolic murmur.

changes. In cases with only moderate diastolic pulmonary hypertension, the diastolic element of the murmur shortens and loses amplitude, in patients with severe pulmonary vascular obstruction and closely identical systolic and diastolic pressure in the aorta and the pulmonary artery, not only may the diastolic element disappear entirely, but also the systolic murmur may become rather insignificant (Fig 6-25). Patients have been seen with a large patent ductus arteriosus and only slight pressure gradient between the two great arteries with no appreciable murmur at all. It is worth emphasizing, however, that, in the vast majority of patients with patent ductus arteriosus and pulmonary arterial hypertension, systolic and diastolic—though not necessarily continuous, machinery—murmurs may be observed.

**Aortopulmonary Fenestration or Rupture of a Sinus of Valsalva.** Both these conditions may give rise to auscultatory phenomena indistinguishable from those of a large patent ductus arteriosus. The only two practical auscultatory hints suggesting the presence of one of these conditions (instead of an open ductus) are that (1) the continuous murmur is likely to be maximal in intensity and (2) it is often heard best at the lower rather than the upper left sternal border. The differentiation, however, has to be made in most instances by other clinical and physiologic laboratory methods.

**Common Truncus Arteriosus.** This rare anomaly, if associated with large pulmonary arteries, may also be hard to distinguish from the auscultatory point of view from a large ductus arteriosus. In view of the anatomic situation, however, the 2d sound is expected to be single, which may represent a subtle point of difference. The continuous murmur—present in about half of the patients with true truncus arteriosus—may be best registered at the 2d left or 2d right interspace, or even over the back (Fig 6-26A). Finally, a harsh lower left sternal border murmur, similar to that described with ventricular septal defect, is almost invariably registered at the lower left or upper right sternal border.

A true truncus arteriosus with hypoplastic pulmonary artery is indistinguishable, not only from the auscultatory, but also from the clinical and physiologic point of view from a severe tetralogy of Fallot.

nary artery and the shape of the murmur by the pressure pulse differences between the two large vessels. In patients with a large patent ductus arteriosus, in addition, low-frequency apical middiastolic and systolic murmurs, probably resulting from functional mitral involvement, can be clearly observed.

In patients with patent ductus arteriosus and appreciable pulmonary arterial hypertension, the intensity and the character of the murmur

practically every instance (Fig. 6-24A). This is obviously the result of the systolic ejection of blood from the left ventricle to the right. The intensity depends on the size of the orifice and the pressure gradient between the two ventricles. The larger the defect, the more right ventricular hypertension is present, the fainter the murmur.

A low-frequency low-intensity mid-diastolic or presystolic murmur is noted at the apex in individuals with large left-to-right shunts. A murmur of pulmonary insufficiency is present in cases with severe pulmonary vascular obstruction

*Patent Ductus Arteriosus*

less pulmonary arterial hypertension is present as well, in this latter case, of course, the pulmonary element of the 2d sound is definitely accentuated. Furthermore, in individuals with

the loudest murmur, the 2d sound may be completely enveloped by the characteristic murmur at the 2d left interspace.

**MURMURS** The typical *machinery* murmur of patent ductus arteriosus begins after an appreciable interval beyond the 1st sound. It consists of high-frequency, high-amplitude uneven vibrations and has a late systolic crescendo, reaching its maximum with the 2d sound (Fig. 6-24B). After the 2d sound, the murmur, without changing frequency, gradually decreases in intensity and trails off sometime before the 1st sound of the next cycle. Thus, it can be said that the typical ductus murmur is not only continuous through both phases of the heart cycle, but also—and quite importantly—has no hiatus between the systolic murmur and the 2d sound. The character and intensity of the ductus murmur can probably be explained by the persistent systolic and diastolic gradient between the aorta and pulmo-

Fig 6-24. A Lower left sternal border and apical sound tracing in patient with ventricular septal defect. Reference tracing at apex is apex cardiogram. Note high-frequency high-amplitude systolic murmur at 3d left interspace (3 LIS) and 2d sound (S<sub>2</sub>) with diastolic murmur at apex. B Typical continuous murmur of patent ductus at pulmonary area. Note crescendo systolic and decrescendo diastolic murmur with maximum intensity with the 2d sound.

istic, murmur is a *continuous* one, heard over the enlarged intercostal arteries in the back. This, however, is a relatively late phenomenon and is practically never heard under the age of 8 to 10 years

Other frequently observed, but less specific, murmurs are (1) aortic stenosis murmur at the 2d right interspace, (2) aortic regurgitation murmur (due to bicuspid aortic valve?) at the 2d right and 4th left interspace, (3) a lower left sternal border systolic murmur similar to that seen in ventricular septal defect, and (4) an apical low-frequency, low-intensity mid-diastolic murmur

There is no adequate explanation for the last two auscultatory phenomena. The middiastolic murmur has been noted in at least 25 per cent of our cases and has been observed with almost equal frequency in patients with a normal-sized heart and those with significant cardiac enlargement

**Aortic Stenosis, sounds** The 1st heart sound is usually unremarkable. A *late systolic click* (*ejection sound*)—not changing in intensity with respiration—is commonly registered at the 2d right interspace and is probably due to the jet of blood hitting the thin-walled ascending aorta. The aortic closure, in patients with severe stenosis, may be somewhat diminished—but in not nearly so marked a degree as the pulmonary closure diminishes in pulmonary stenosis. This is clearly the result of the fact that a sizable and relatively high aortic pressure is necessary for maintenance of life. The aortic 2d sound is delayed in patients with severe aortic stenosis—sometimes to the extent that it occurs beyond the pulmonary closure (*paradoxical splitting*). During the height of inspiration, the increased caval flow prolongs right ventricular systole to an extent that pulmonary closure occurs later than normal. In normal individuals, whose aortic closure precedes pulmonary closure, this results in a widening in the split of the 2d sound. In patients, with severe aortic stenosis, however, whose aortic closure follows pulmonary closure (*paradoxical splitting*), inspiration causes a narrowing of the distance between the two elements of the 2d sound.

**Murmurs** The typical systolic murmur of aortic stenosis is *diamond-shaped* and consists of vibrations of high frequency and high amplitude, registered maximally at the 2d right

interspace, transmitted well to the neck vessels and the back (Fig. 6-27A). The apex of the diamond, on the whole, is nearer to the 1st sound than in cases with severe pulmonary stenosis. A positive correlation between the severity of the stenosis and the position of the apex of the diamond in systole has been claimed by some authors.<sup>2</sup>

In at least 20 per cent of the patients with congenital aortic stenosis—valvular as well as subvalvular—an early-diastolic blowing murmur may be registered at the 2d right and 4th left interspace.

**Congenital Mitral Stenosis and Cor Triatriatum.** The auscultatory phenomena may to a greater or lesser degree simulate those of acquired mitral valvular disease.

**Pulmonary Stenosis with Intact Ventricular Septum. sounds.** The only remarkable thing about the 1st sound in this condition is that it is commonly followed, particularly on expiration, by an *ejection sound*—a *systolic click*—at the pulmonary area. Frequently, though not invariably, this denotes mild stenosis, almost without exception it occurs with valvular stenosis and poststenotic dilatation.

The characteristics of the 2d sound in pulmonary stenosis with intact ventricular septum have been discussed extensively. As has been pointed out before,<sup>3</sup> under normal circumstances—because of the nature of the pressure pulses—pulmonary closure follows aortic closure by 0.02 to 0.04 sec. As a rule, in healthy subjects, pulmonary closure is registered with higher amplitude at the 2d left interspace, than aortic closure. In pulmonary stenosis with intact ventricular septum depending upon the severity of the stenosis—both the distance between aortic and pulmonary elements and the intensity of pulmonary closure itself may undergo significant changes. The more severe the pulmonary outflow obstruction, the longer the right ventricular systole, the wider the splitting of the 2d sound. Also, the lower the pulmonary arterial pressure, the fainter the result of pulmonary closure, till in individuals with maximal stenosis it cannot be heard or even registered at all.

A 4th sound (or presystolic gallop) associated with right atrial hypertension is clearly

<sup>2</sup> See Part 7, Chap. 9. Editor

# VALVULAR AND VASCULAR LESIONS WITH A RIGHT-TO-LEFT SHUNT OR NO SHUNT

**Coarctation of the Aorta. SOUNDS** The 2d sound is usually loudest in the aortic area; of the two elements, the aortic  $\equiv$  loudest. The presence of an apical 3d sound is not unusual, particularly in children.

**MURMURS.** The most characteristic—almost pathognomonic—auscultatory phenomenon of coarctation of the aorta is a *high-frequency, moderately high-amplitude diamond-shaped murmur*, maximally heard over either side of the spine. This is presumably caused by the coarcted segment of the aorta itself (Fig 6-26B).

The second, and almost equally character-

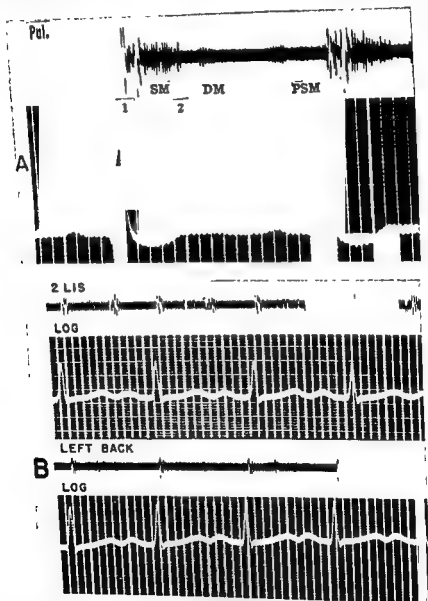

Fig 6-26 A. Phonocardiogram of patient with common truncus arteriosus. Note 1st sound and systolic click, decrescenda systolic murmur, and mid-diastolic presystolic (DM, PSM) rumble. B Sound tracings in patient with coarctation of the aorta. Note continuous murmur at 2d left interspace and back. The systolic murmur at 2d left interspace (2 LIS) is suggestively diamond-shaped.

registered in patients with severe pulmonary stenosis.

**MURMURS.** The systolic murmur of pure pulmonary stenosis is *diamond-shaped* and is best registered at the pulmonic area. The vibrations are of high frequency and usually of high intensity. The murmur transmits very well to the neck and the back. A rather good correlation exists between the severity of the stenosis and the position of the apex of the diamond in systole. The later the peak of the diamond, the more severe the stenosis (Fig. 6-27B). Almost invariably, in patients with severe pure pulmonary stenosis, the apex of the diamond is beyond the first half systole. Since pulmonary closure is late, blood continues to flow through the pulmonary valve beyond aortic closure, pulmonary closure is faint, thus, the impression of an early diastolic murmur may be created by the prolonged pulmonary systolic

murmur extending beyond the well-registered aortic closure.

In rare instances of maximal pure pulmonary stenosis, accompanying tricuspid valve abnormalities may result in murmurs of tricuspid regurgitation and tricuspid stenosis.

**The Tetralogy of Fallot. SOUNDS.** The 1st sound is loudest at the lower left sternal border. Usually, it is not split. The 2d sound is almost invariably single and loud at the lower left sternal border. It probably represents aortic closure exclusively, with very little pulmonary element added to it. Only a very diminished 2d sound is heard at the pulmonary area—this probably corresponds also to aortic closure. The closure of the pulmonary valve is so faint and probably so close to aortic closure that it is almost never audible and seldom demonstrable by phonocardiography.

**MURMURS.** The characteristic murmur of the

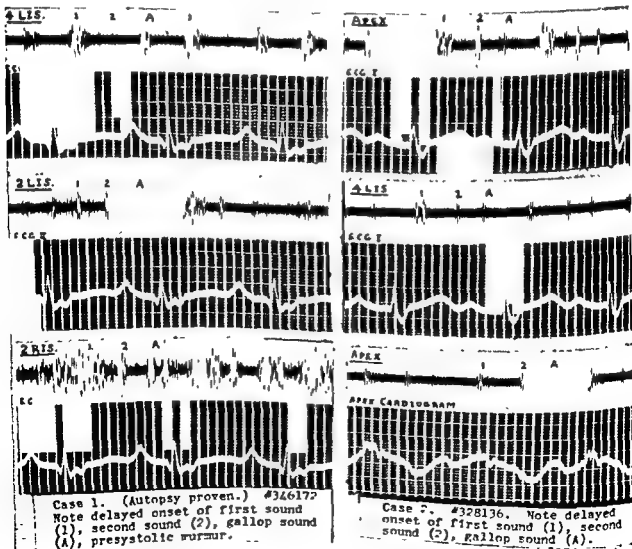

Fig. 6-28. Phonocardiogram of two patients with Ebstein's anomaly.

Fig. 6-27. A Phonocardiogram at 2d right intercostal space of patient with pure pulmonary stenosis and widely split 2d sound. B Phonocardiogram at 2d left intercostal space of patient with pure pulmonary stenosis and widely split 2d sound. C Phonocardiogram at 2d left intercostal space of patient with pulmonary stenosis and ventricular septal defect (tetralogy of Fallot). The apex of the diamond-shaped murmur is close to the 1st sound, and the 2d sound is not split.

# Electrokymography in congenital heart disease

GIANO MAGRI

In contrast with the number of studies of electrokymography published since 1946, only few contributions have appeared dealing with congenital heart disease. This might be related to the difficulties of the method and the necessity of good collaboration of the patient, which renders its application to infants more difficult. In spite of this, several observations have appeared since 1950, including the outstanding work of Kjellberg et al. In addition, special publications have been devoted to electrokymography in congenital heart diseases (Donzelot et al., Lusaada and Fleischer, 1949; Magistretti et al., 1956, Magri et al., 1957).

Data of some interest may be obtained from the study of either the border tracings of the cardiovascular silhouette (right atrium, right ventricle,

catheterization, in some cases a simultaneous record of intracardiac pressure curves and of the ECG with the EKy allows a more exact interpretation of the electrokymographic waves.

In spite of the great variety of congenital malformations, some degree of schematization of the EKy changes is possible. Characteristic patterns have been observed in cases with increased or decreased pulmonary flow, in pulmonary hypertension, and in pulmonic or aortic stenosis. In more complex malformations, the modifications of the EKy may be similar to those observed in certain basic hemodynamic syndromes and contribute little to an exact anatomic diagnosis of the disease. For this reason, the following description, far from complete, will be limited to some of the most common malformations for which sufficient data have been collected.

**Pulmonic Stenosis.** The most interesting tracings are obtained over the pulmonary artery. In general, the pulsations of the artery are *decreased*, but in valvular stenosis, they might be increased over the initial part. For this reason, the valvular and the infundibular stenosis should be considered separately.

**VALVULAR STENOSIS.** The degree of stenosis is important in causing the electrokymographic changes. According to Kjellberg and coworkers, in cases of moderate stenosis with a pressure gradient of less than 30 mm Hg, the incisura and the dicrotic wave appear poorly defined. When the gradient is more than 30 mm Hg, an *anacrotic notch* appears over the

the deflections recorded. Therefore, the same degree of amplification should be used for the various structures. It is obvious that, when one mentions a decrease of amplitude of pulsations from the hila to the periphery of the lung, the comparison is made between tracings recorded with the same amplification. One can either study the general patterns of the tracings or measure the basic phases of the cardiac cycle. For the study of patterns, a film speed of 50 mm/sec is sufficient, while for accurate measurements, film speeds of 75 to 100 mm/sec or more are necessary. As many patients with congenital heart disease are submitted to

tetralogy of Fallot syndrome is a *stenotic pulmonary ejection murmur* (Fig 6-27C). It is different in some characteristic ways from that audible in pure pulmonary stenosis. (1) the murmur of the tetralogy of Fallot is loudest at the mid- and lower left sternal border, rather than the upper left sternal border, probably because of the infundibular nature of the obstruction; (2) the right and left ventricular pressure pulses in this condition are so similar to each other that the peak ejection of the blood through the pulmonary outflow tract occurs relatively early, as a consequence, the apex of the diamond-shaped murmur occurs usually early, that is, within the first half of systole, (3) the transmission of the Fallot murmur is not so wide, particularly to the neck, as the stenotic murmur of pure pulmonary stenosis.

One may state with fair assurance that the intensity of the murmur in the tetralogy of Fallot is in inverse proportion to the severity of the disease. As a matter of fact, a child who, when feeling well, has a loud rasping systolic murmur may have no murmur at all during a hypercyanotic spell. This is probably the result of markedly diminished flow of blood through the pulmonary outflow tract. Some of the most severe cases of tetralogy of Fallot, those with functional or anatomic pulmonary atresia, may have no murmurs at all.

It is interesting to note that, although in patients with a ventricular defect and left-to-right shunt typical murmurs attributable to the septal defect are heard, in situations where the shunt across the ventricular defect is exclusively in the right-to-left direction, no murmurs are audible. It should also be mentioned that older children and adults with maximal pulmonary obstruction usually have continuous "collateral" murmurs over the back and under the clavicle.

**Tricuspid Atresia.** The auscultatory phenomena are indistinguishable—from the basis of present information—from those observed in patients with tetralogy of Fallot.

**Ebstein's Anomaly.** Patients with downward displacement of the tricuspid valve have rather characteristic auscultatory findings.

**SOUNDS.** A triple or quadruple rhythm is registered almost without exception. The components of this are (1) late 1st sound, (2)

Fig 6-29. Phonocardiogram at apex of patient with complete transposition of pulmonary veins. Note the triple rhythm and systolic and presystolic murmur.

well-split and low-intensity 2d sound, (3) atrial sound and occasional 3d sound. The 2d sound at the pulmonary area is diminished in intensity.

**MURMURS.** Most of the murmurs in Ebstein's anomaly originate at the tricuspid valve. A scratchy, regurgitant murmur increasing with inspiration at the lower left sternal border and an atrial systolic (presystolic) murmur at the apex are typical auscultatory phenomena (Fig 6-28).

## THE TRANSPOSITIONS

**Transposition of the Pulmonary Veins.** Partial transposition is indistinguishable from the auscultatory viewpoint from a secundum-type atrial septal defect. The phonocardiographic picture of a complete transposition of the pulmonary veins in many ways is similar to Ebstein's disease. Triple or quadruple rhythms are common, and murmurs of tricuspid regurgitation and stenosis are present in the typical cases (Fig 6-29).

**Transposition of the Great Arteries.** **SOUNDS.** The 2d sound in the pulmonary area is usually diminished. At the lower left sternal border, loud and single 1st and 2d sounds are registered.

**MURMURS.** About a third of the patients have no murmurs. The others show a lower left sternal border systolic murmur which may have the characteristics of a ventricular defect or an infundibular stenosis. Very occasionally, an apical low-frequency diastolic murmur is also demonstrable.

increased ventricular dynamics are in contrast with the dynamics of the pulmonary artery.

**OTHER TRACINGS.** The aortic pulses and the left ventricular curve pulses are often normal, but in some cases, a reduced amplitude of the ventricular motions can be observed. This seems due to a decreased venous return to the left heart.

**Trilogy of Fallot.** When pulmonary stenosis is associated with an interventricular septal defect, unimportant variations are observed over the pulmonary artery and the right cardiac cavities. If, in addition, there is also an atrial right-to-left shunt, the EKy of the left atrium is modified and may even assume the pattern of mitral insufficiency.

**Tetralogy of Fallot.** The particular structural malformation may render it difficult to obtain records of the pulses of the pulmonary artery. If recorded, the pulmonic pattern is typical of infundibular stenosis. In one case, reported by Kjellberg and coworkers, a negative pulsation was recorded over the infundibulum. The pulsations of the peripheral pulmonary fields are generally decreased and may be absent. However, in two personal cases, good pulsations of atrial type have been observed over the lungs. This pattern is probably due to the pulsations of the pulmonary veins. The

right ventricular and right atrial curves show the overload and strain of these chambers. An increase of the atrial waves and a delay of ventricular ejection have been noted. Good pulsations have been recorded over the left ventricle and aorta (Fig. 6-31).

In *pentalogy of Fallot*, the additional atrial septal defect may cause large left atrial waves, as in the trilogy of Fallot.

**Pulmonary Hypertension.** In pulmonary hypertension, the *pulmonary arterial pulse* has the following typical pattern: (1) delay of the foot of the wave (measured from the Q of the ECG); (2) slower rise; (3) marked delay of the peak of the wave, which falls in late systole; (4) decreased amplitude and early diastolic wave. The *right atrial tracing* may show evidence of powerful atrial contractions. Both this and the evidence of delayed right ventricular ejection have been observed in all cases in which the flow from the right chambers was opposed (pulmonary stenosis, constrictive pericarditis); therefore, these patterns are not specific. In some cases, *wide pulsations* are recorded over the pulmonary trunk, in contrast with the small pulsations of the peripheral pulmonary fields (Luisada and Fleischner). This difference is especially evident in cases of thrombosis of the small arterial vessels. In such

Fig 6-31. Tetralogy of Fallot in an 18-year-old boy. The EKy of the right atrium, recorded in the P-A position, shows a deep presystolic wave. The EKy of the right ventricle (in LAO) shows a high positive presystolic wave, synchronous with the atrial contraction. The aortic pulse is within normal limits. It was not possible to record the pulsations of the pulmonary artery.

ascending branch of the pulse: the higher the pressure gradient, the lower is this notch. In addition, there may be a rounding of the peak of the wave and the presence of some vibrations, revealing the turbulence of flow. In moderate stenosis (gradient RV-PA around 80 mm Hg), the anacrotic notch is deeper and lower while the peak is sharper (Fig. 6-30A). In severe stenosis (gradient RV-PA around 125 mm Hg or more), the changes are even more evident: the incisura and the dicrotic wave are delayed, are smaller, and may disappear, while the anacrotic notch is not always visible (Fig. 6-30B). The most common aspect of the pulse of the pulmonary artery is a typical anacrotic pulse with rounded and delayed apex; sometimes it is plateau-like and may be concave, according to Donzelot and coworkers. The markedly reduced amplitude of pulsations of the peripheral pulmonary fields often corresponds to an increase of pulsations of the pulmonary trunk, which is due to the poststenotic eddies which dilate the main artery.

**INFUNDIBULAR STENOSIS** The pulmonary trunk has no increase of pulsations. In 9 out of 11 cases studied by Kjellberg and coworkers, small pulse waves were found on the pulmonary artery. The pattern was such that it was difficult to distinguish any peak of the waves. In addition, both the incisura and the dicrotic notch were delayed. While cases with valvular stenosis may present pulses with an anacrotic notch in the ascending limb, cases with in-

fundibular stenosis never show this detail. Cases with postvalvular stenosis present pulses similar to those observed in valvular stenosis. It should be emphasized that an anacrotic notch can be observed in other heart diseases, such as mitral stenosis and cor pulmonale. However, in these conditions, both the incisura and the dicrotic notch are wide and are not delayed. In these cases, the site of the electrokymograph should not be placed too low, in order not to record the motions of the left atrium (Kjellberg et al.). Study of the pulmonary artery gives important data, but is not possible in many cases because the pulses are too small and even imperceptible. On the other hand, tracings recorded over other segments of the cardiovascular silhouette may show characteristic patterns.

**RIGHT VENTRICLE.** A prolonged ejection period (over 0.30 sec) and a short isometric period have been described. It is necessary to remember that, in the PA position, it is often difficult to record the right ventricular tracing, the curve looks like that of the atrial EKy. On the contrary, a good tracing can be obtained in the LAO position.

**RIGHT ATRIUM.** Various authors agree about the abnormal amplitude of the presystolic wave, indicating strong right atrial contraction. The increased atrial and ventricular pulsations which can be recorded over the lower right arch are in contrast with the decreased pulsations of the pulmonic arch. In other words, the

Fig. 6-30. The EKy tracings in two cases of pulmonic stenosis. A. Patient age 18 years with valvular stenosis (right ventricle, 120; pulmonary artery, 15 with a gradient of 105 mm Hg). The EKy of the right atrium shows a deep, negative presystolic wave. The EKy of the pulmonary artery shows a slow rise of the pulse and an early anacrotic notch. The peak of the pulse is sharp and is recorded 0.26 sec from the beginning of the wave (0.38 sec from Q). B. Patient age 24 years with valvular stenosis (very high pressure gradient, right ventricle, 150; pulmonary artery, 10 mm Hg). The EKy, recorded over the origin of the pulmonary artery, shows good Q). The incisura and dicrotic wave are visible, but severely delayed.

Fig. 6-33. Ventricular septal defect in a 36-year-old man. The ventricular tracings are within normal limits. The EKG of the right atrium shows a positive presystolic wave. There is a plateau-like pattern over the pulmonary artery, unusual in this anomaly, and there are increased hilar pulsations.

seen by the author: 140/20 mm Hg). In the typical cases having pulmonary hypertension and a severely dilated pulmonary artery, the ascending branch of the pulmonic pulse is prolonged, the peak of the wave is rounded, and the descending branch is also prolonged (Figs. 6-34 and 6-35).

**Truncus Arteriosus.** In a case observed by Kjellberg and coworkers, the pulmonary pulse

had the same pattern as that observed in pulmonary hypertension; the aortic pulse had a delayed incisura and a late diastolic wave, because of the increased flow and the greater pulse pressure. According to Donzelot and coworkers (four cases), the pulmonary pulses are low and indistinct. However, there are not sufficient data for an exact description of the EKG pattern in this malformation.

Fig. 6-34. Eisenmenger's complex plus tricuspid insufficiency in a 19-year-old boy. Large pulsations of the right ventricular border (LAO position). The pulse of the pulmonary artery shows a slow rise and a rounded peak. The diastolic wave is small and delayed. There are good pulsations of the hila and small pulsations of the peripheral pulmonary fields.

ascending branch of the pulse: the higher the pressure gradient, the lower is this notch. In addition, there may be a rounding of the peak of the wave and the presence of some vibrations, revealing the turbulence of flow. In moderate stenosis (gradient RV-PA around 80 mm Hg), the anacrotic notch is deeper and lower while the peak is sharper (Fig. 6-30A). In severe stenosis (gradient RV-PA around 125 mm Hg or more), the changes are even more evident: the incisura and the dicrotic wave are delayed, are smaller, and may disappear, while the anacrotic notch is not always visible (Fig. 6-30B). The most common aspect of the pulse of the pulmonary artery is a typical anacrotic pulse with rounded and delayed apex; sometimes it is plateau-like and may be concave, according to Donzelot and coworkers. The markedly reduced amplitude of pulsations of the peripheral pulmonary fields often corresponds to an increase of pulsations of the pulmonary trunk, which is due to the poststenotic eddies which dilate the main artery.

**FUNDIBULAR STENOSIS** The pulmonary trunk has no increase of pulsations. In 9 out of 11 cases studied by Kjellberg and coworkers, small pulse waves were found on the pulmonary artery. The pattern was such that it was difficult to distinguish any peak of the waves. In addition, both the incisura and the dicrotic notch were delayed. While cases with valvular stenosis may present pulses with an anacrotic notch in the ascending limb, cases with in-

fundibular stenosis never show this detail. Cases with postvalvular stenosis present pulses similar to those observed in valvular stenosis. It should be emphasized that an anacrotic notch can be observed in other heart diseases, such as mitral stenosis and cor pulmonale. However, in these conditions, both the incisura and the dicrotic notch are wide and are not delayed. In these cases, the slit of the electrokymograph should not be placed too low, in order not to record the motions of the left atrium (Kjellberg et al.). Study of the pulmonary artery gives important data, but is not possible in many cases because the pulses are too small and even imperceptible. On the other hand, tracings recorded over other segments of the cardiovascular silhouette may show characteristic patterns.

**RIGHT VENTRICLE.** A prolonged ejection period (over 0.30 sec) and a short isometric period have been described. It is necessary to remember that, in the PA position, it is often difficult to record the right ventricular tracing; the curve looks like that of the atrial EKy. On the contrary, a good tracing can be obtained in the LAO position.

**RIGHT ATRIUM.** Various authors agree about the abnormal amplitude of the presystolic wave, indicating strong right atrial contraction. The increased atrial and ventricular pulsations which can be recorded over the lower right arch are in contrast with the decreased pulsations of the pulmonic arch. In other words, the

The EKy of the right atrium shows a deep, negative presystolic wave. The EKy of the pulmonary artery shows a slow rise of the pulse and an early anacrotic notch. The peak of the pulse is sharp and is recorded 0.26 sec from the beginning of the wave (0.38 sec from Q). B. Patient age 24 years with valvular stenosis (very high pressure gradient right ventricle, 150; pulmonary artery, 10 mm Hg). The EKy, recorded over the origin of the pulmonary artery, shows good pulsations. The pulse rises slowly at first, then more rapidly. The peak is delayed (0.34 sec from Q). The incisura and dicrotic wave are visible, but severely delayed.

Fig. 6-37. Patent ductus arteriosus in a 32-year-old woman. Simultaneous Eky and pressure tracing. Normal atrial waves and rapid pulmonic pulse (speed, 25 mm/sec).

Fig. 6-38. Patent ductus arteriosus in a 20-year-old woman. Eky recorded over pulmonary artery, hilum and peripheral pulmonary fields. Large pulmonary pulse, rounded peak, high diastolic wave. In some segments of the vessel, a double impulse is recorded. Normal speed of the pulmonic pulse wave toward the periphery of the lungs. Pressures: aorta, 130/50; pulmonary artery, 130/65; right ventricle, 130/0.

Fig. 6-39. Coarctation of the aorta in a 22-year-old man. Normal pattern of the aortic pulse. Marked pulsations of the intercostal arteries.

cases, strong right ventricular pulsations and small left ventricular pulsations are recorded, on account of decreased venous return to the left heart with a decreased left ventricular output.

**Atrial Septal Defect.** The tracings recorded over the lower right border or the pulmonary conus and the densograms of the hilar shadows or the periphery of the lungs are similar in this defect and in anomalous venous drainage. The fundamental picture is that of an increased pulmonary flow. The pulse of the pulmonary artery has a typical appearance, the foot of the wave is not delayed, the peak of the wave falls early (*pulsus celer*). This pattern is related to the increased volume of ejection and to the speed of the wave ejected from the right ventricle without increase of peripheral resistances. This, however, is not true in all the cases, especially in adults, because changes of the pulmonary vessels may cause an increase of peripheral resistance. For this reason, the peak of the wave may be rounded and delayed, indicating this secondary abnormality (Fig. 6-32). The diastolic wave is wide and falls in the second half of the descending branch of the pulse. The pulsations of the hilar shadows are increased, and the peripheral pulmonary fields also have large pulsations. The interval between central and peripheral pulmonary pulses is decreased (high speed and normal peripheral resistances).

**RIGHT VENTRICLE.** According to Magistretti et al, diastole of the right ventricle is completed after that of the left. Isometric contraction, on the contrary, is slightly shorter than on the left side, and so is isometric relaxation.

**RIGHT ATRIUM.** In two cases seen by the author, the presystolic atrial waves were large

(Fig. 6-32). An additional positive systolic wave related to the shunt has been described but is far from being constant.

**LEFT HEART.** An increase of the pulsations of the right and a reduction of the pulsations of the left cardiac contour have been considered typical. This fact is only relative, therefore, it is possible to observe "normal" pulsations on the left side. No morphologic alterations of the waves have been observed.

**Ventricular Septal Defect.** According to the majority of authors, the tracings are within normal limits. However, Luisada and Fleischer described an increased amplitude of the pulmonary artery pulsations and a *pulsus celer* over the hila and the peripheral pulmonary fields, without increase of the speed of the pulse. Kjellberg and coworkers, in 13 out of 25 cases, observed a slower rise and a longer duration of the pulmonary pulse (0.15 to 0.20 sec), the peak was in late systole, the incisura was premature, and the diastolic wave was small. The tracings, therefore, are similar to those of the pulmonary hypertension. The most important data consist of an increased amplitude of the pulmonary pulsations extending to the hila and the periphery of the lungs. Both ventricular borders present large pulsations. The right atrial curve has good waves, and the presystolic waves are very evident (Fig. 6-33). The aortic pulsations are normal.

**Eisenmenger's Complex.** The pulsations are increased over both the right and the left ventricular contours and also over the pulmonary trunk. Large pulsations are observed over the hila. Reduced pulsations have been observed over the peripheral pulmonary fields (Fig. 6-34), at least in cases with very high pressure in the pulmonary artery (in a case

Fig. 6-32. Atrial septal defect in a 16-year-old girl. The EKY of the right atrium shows large positive systolic waves. The pulmonary pulse is rounded, and the peak is delayed (0.30 sec after Q). Good pulsations are observed over the hilar region.

Fig. 6-38. Patent ductus arteriosus in a 20-year-old woman. EKy recorded over pulmonary artery, hilum and peripheral pulmonary fields. Large pulmonary pulse, rounded peak, high diastolic waves. In some segments of the vessel, a double impulse is recorded. Normal speed of the pulmonic pulse wave toward the periphery of the lungs. Pressures aorta, 130/50, pulmonary artery, 130/65; right ventricle, 130/0.

Fig. 6-39. Coarctation of the aorta in a 22-year-old man. Normal pattern of the aortic pulse. Marked pulsations of the intercostal arteries.

Fig. 6-35. Eisenmenger's complex plus anomalous venous return in a 19-year-old boy. Right ventricle pressure, 140/5, pulmonary artery pressure, 120/60. There are severe changes of the pulmonary pulses and a high diastolic wave.

**Patent Ductus Arteriosus.** The EKys recorded over the large vessels give the best information.

**AORTIC PULSE.** This is large and almost similar to that recorded in aortic insufficiency. However, the pulse is more rounded than in aortic insufficiency (Figs 6-36 to 6-38). The foot of the wave may occur early, while both the incisura and the diastolic wave are accentuated. However, in many cases, the tracing is within normal limits. If there is a reversed shunt, the aortic tracing is abnormal. In such a case, the foot of the curve is delayed and the peak is pointed. The incisura is more evident, and the diastolic wave is increased.

**PULMONIC PULSE.** The pulse often has a typical pattern: there are large pulsations with a rapid rise (Figs 6-36 to 6-38). The pulse may be similar to that recorded in pulmonary hypertension. The peak may be followed by a plateau and a typical notch. According to Donzelot and coworkers, an anacrotic notch would be due to the shunt. The diastolic wave is described as displaced toward the peak of

the pulse. A peaked diastolic wave on the descending branch of the pulse wave has also been described (Fig 6-34). These typical patterns have been observed by several authors and are probably due to the shunt. In two out of three cases, this wave was observed also over the pulmonic fields. It should be emphasized that this wave was not observed in a case in which the pulmonary pulse was delayed and rounded, and in which cardiac catheterization showed a high diastolic pulmonary pressure.

**PERIPHERAL PULMONARY FIELDS.** The arterial pulsations are high and rapid and show a well-marked diastolic wave. An increase of the speed of the pulse waves has been observed (Luisada and Fleischner).

**LEFT ATRIUM.** Because of the increased flow, larger atrial contractions are recorded. On the contrary, the ventricular tracing is usually normal.

**Aortic Stenosis.** The tracing of the aortic arch, the left ventricular tracing, and the left atrial tracing present interesting data.

Fig. 6-36. Patent ductus arteriosus in a 16-year-old girl. Large ventricular pulsations; rounded aortic pulse with high diastolic wave (right ventricle pressure, 25; pulmonary artery pressure, 20).

# Blood in congenital heart disease

MARIO STEFANINI AND FRANCO COBBI

There are significant changes in morphologic and chemical constituents of the blood in the course of some congenital heart diseases. A review of the literature indicates that this subject has been discussed often but has seldom received adequate treatment.

A few generalizations may be made as introductory remarks. *Significant blood changes are found in congenital heart disease only when venous-arterial shunts or other anomalies, important enough to induce cyanosis, are present.* Two findings are outstanding (1) *increased red cell mass* with relative lack of involvement of the other formed elements of the blood, this produces the classic picture of secondary polycythemia, (2) *defects in the hemostatic and blood-clotting mechanisms* leading to *blood hypocoagulability* and, under certain circumstances, to severe bleeding. All changes

revert to normal after successful corrective surgery. They will be discussed separately.

## SECONDARY POLYCYTHEMIA

The polycythemic state of cyanotic congenital heart disease is a compensatory mechanism to the low arterial blood  $O_2$  saturation and tissue hypoxia. Thus, it is constantly associated with cyanosis and clubbing of the fingers (Fig 6-40) severe dyspnea, etc. The liver and spleen may be palpable in a small number of cases (Lawrence).

Blood findings are those typical of polycythemia of the so-called secondary type (Table 6-3). Erythrocyte count, hemoglobin level, and hematocrit are very high. White cell and neutrophil counts may be slightly above normal but are most often normal; platelets are never above the normal range and are, in fact, dras-

Fig. 6-40. Congenital heart disease with cyanosis (Eisenmenger's syndrome). Note clubbing of the fingers and toes. Hematologic and other findings are described in Table 6-3.

**AORTIC PULSE.** The foot of the wave generally is normal, while the ascending branch is prolonged; it is possible to observe an anacrotic notch, but this is less frequent than in pulmonic stenosis. The peak of the wave, generally rounded, is delayed. The incisura and the dicrotic wave are less evident than normally and may be delayed. The pulses of the ascending aorta are generally larger in valvular than in subvalvular (infundibular) stenosis.

**LEFT VENTRICLE.** There is prolongation of the ejection phase, both the isometric contraction and the expulsion phase (rapid and delayed) appear prolonged.

**LEFT ATRIUM.** There may be large pulsations due to higher diastolic pressure in the left ventricle.

**Coarctation of the Aorta.** Small pulses have been recorded below the point of narrowing, in contrast with the pulses above the narrowing. In the majority of the cases, however, normal pulsations have been recorded along the aorta. In some cases, the pulses of the intercostal arteries are recorded (Fig 6-39).

The left ventricular curve is characterized by large pulsations of normal appearance. The left atrium also shows evidence of increased dynamics.

**Ebstein's Disease.** In the few cases reported, an increase of pulsations of the right atrium was observed. The presystolic waves were non-observable, while large positive waves were observed in systole, evidence of tricuspid insufficiency.

**Conclusions.** The EKy study of congenital heart diseases may provide similar data to those obtained with roentgenkymography. However, the patterns recorded by the former method are more typical and easier to study. The most important data are obtained over the pulmonary artery, hila, and peripheral pulmonary fields, especially in pulmonary hypertension and in cases with abnormal pulmonary flow. However, it is impossible to reach a clinical-anatomic diagnosis of the malformations only on the basis of the functional data revealed by the EKy. The most typical patterns are observed in pulmonic stenosis and in shunts (chiefly patent ductus).

# Blood in congenital heart disease

MARIO STEFANINI AND FRANCO GOBBI

There are significant changes in morphologic and chemical constituents of the blood in the course of some congenital heart diseases. A review of the literature indicates that this subject has been discussed often but has seldom received adequate treatment.

A few generalizations may be made as introductory remarks. Significant blood changes are found in congenital heart disease only when venous-arterial shunts or other anomalies, important enough to induce cyanosis, are present. Two findings are outstanding (1) increased red cell mass with relative lack of involvement of the other formed elements of the blood; this produces the classic picture of secondary polycythemia, (2) defects in the hemostatic and blood-clotting mechanisms leading to blood hypocoagulability and, under certain circumstances, to severe bleeding. DIAGRAM 6-2. MECHANISMS OF SECONDARY POLYCYTHEMIA IN CYANOTIC CONGENITAL HEART DISEASE

Low arterial  $O_2$  saturation, slow blood flow (due to high red cell mass and blood viscosity) cause tissue anoxia. Hypoxia of kidney, possibly other organs, causes release of humoral (? hormonal) factors (among which may be erythropoietin), stimulating the bone marrow to high red cell production (secondary polycythemia).

lated with the enormously increased production of erythrocytes, the rapid turnover and utilization of iron over a long period of time, and its relative depletion from tissue stores. This consideration would make an intensive program of venesection inadvisable in these patients, unless severe symptoms of congestive heart failure are present. The administration of iron has also been recommended in selected cases where hypochromia is outstanding. Iron has been given to children with cyanotic con-

genital heart disease whose hematocrit is lower than 75. Above this figure, the result of high blood viscosity interferes with the beneficial effects of the  $O_2$  carrying power of an even fully hemoglobinized red cell.

The polycythemia of cyanotic congenital heart disease is alleviated by decreasing the need for  $O_2$  transport. Thus, it decreases when patients are kept at continuous rest. It completely regresses when the responsible mechanical defect is corrected by cardiac surgery.

### THE COAGULATION DEFECT

Most clinicians agree that patients with cyanotic congenital heart disease frequently present the paradoxical combination of thrombotic and hemorrhagic manifestations. The most common *thrombotic manifestations* involve the lungs, the mesenteric vessels, and the superficial veins. They need not be clinically evident, as one may see silent extensive thrombosis of vessels (especially pulmonary), both recent and old, in autopsy material. The most frequent and serious complication is the thrombosis of cerebral vessels, followed by sudden *hemiplegia*. The combination of high red cell mass, slow blood flow, and high blood viscosity with resulting clumping of erythrocytes and possible clumping of platelets, and the intimal damage due to hypoxia, are among the most significant pathogenic factors (Fig 6-41).

Treatment of thrombotic complications in patients with cyanotic congenital heart disease is beset with difficulties. Anticoagulation with

tically reduced in many cases. The total blood volume is very high, primarily because of the high red cell mass, since the plasma volume is never high and is often reduced.<sup>1</sup> Viscosity of whole blood is high, plasma viscosity is normal. The reticulocyte count is high, suggesting an accelerated rate of red cell production or destruction. No evidence, however, has thus far been submitted of a shortened life span of the erythrocytes in secondary polycythemia. The slight elevation of indirect reacting serum bilirubin, the higher-than-normal serum iron level (in some stages of the disease), and the increased fecal urobilinogen excretion are best explained by the total increased metabolism of hemoglobin due to the polycythemic state, without need of postulating an exaggerated hemolysis. The two- to threefold increase in red cell production has been documented by  $^{59}\text{Fe}$  turnover studies (Lawrence).<sup>2</sup> Moreover, bone marrow studies indicate significant normoblastic hyperplasia, while myeloid elements are only slightly hyperplastic and megakaryocytes are not, as a rule, high in number or activity.

<sup>1</sup> The behavior of the total blood, plasma, and red cell volumes is not standard in different types of cyanotic congenital heart disease (Nelson et al.). High red cell mass and low plasma volume are found in some cases.

<sup>2</sup> In some cases, high red cell mass and increased plasma volume as well.

The mechanism of the secondary polycythemia in congenital heart disease with cyanosis is complex (Diagram 6-2). It is linked with the low arterial blood O<sub>2</sub> saturation and the resulting tissue hypoxia. Figures as low as 30 per cent (or even lower) have been reported (Taussig, 1947a), with most cases showing values from 50 to 75 per cent, which drop considerably with mild exercise or crying. An aggravating factor may be the high blood viscosity, which causes "sludging" within the small vessels and further reduces blood flow. A hypoxic bone marrow reacts with secondary polycythemia, possibly mediated through a humoral agent (Reissman). Tissue hypoxia, however, may lead to polycythemia through other mechanisms as well. The authors have recently shown that renal venostasis, induced by unilateral partial ligation of the renal vein in dogs, induces a transitory polycythemic state, which regresses when sufficient collateral circulation has developed (van Lessen et al.). This erythrocytotic state may be due to the stimulatory effect of a humoral factor, possibly "erythropoietin," produced in excess under the experimental conditions. It is not improbable that hypoxia of other organs as well might have similar stimulatory effects on the bone marrow, as postulated many years ago.

An interesting clinical observation is that most patients with cyanotic polycythemia become relatively hypochromic in later stages (Rudolph et al.). This finding may be corre-

hours following surgery is a serious complication. For the above reasons, coumarin drugs should be given only in small doses while heparin may be used with less circumspection, provided patient is under observation for the appearance of bleeding manifestations. Full details of anticoagulant treatment are found in Taussig's monograph (1947a).

Patients with cyanotic congenital heart disease also present a well-known *hemorrhagic tendency*, which is similar to that found in polycythemia vera and in hypoxic secondary polycythemia. The bleeding manifestations consist of epistaxis, hemoptysis, hematemesis, cerebral hemorrhages, and spreading ecchymotic areas in the skin. Their occurrence has been described as "high" by Hartman.

A clue to the mechanism of hemorrhage in these patients is the behavior of the *erythrocyte sedimentation rate*, which is very low, normally less than 5 mm/1 hr by the method of Westergren, and often as low as 0. Together with high blood viscosity and high red cell mass, other factors must be present to explain such a low erythrocyte sedimentation rate. One of these factors is the severe fibrinogenopenia of these patients.

Fibrinogen deficiency, however, is only a facet of the breakdown of the hemostatic process through a complex mechanism (Diagram 6-3). The *tourniquet test* is often positive, possibly because of the damaging effects of hypoxia on the vessel walls. The *clotting time* determined in silicone-coated test tubes may be slightly prolonged. *Clot retraction* is impaired because of a variety of causes which include fibrinogenopenia, poor production of thrombin, and low plasma with high red cell volumes. The most important factors are probably the high red cell mass and the inability of the reduced fibrinogen to hold red cells into a firm clot. Thus, the retraction of a plasma clot is inadequate. When, however, whole blood is observed, the poor fibrin mesh is unable to hold on to the red cell mass. Two phenomena may then become apparent: either the clot shrinks rapidly and sinks to the bottom of the test tube, or the clot appears as a small knob at the blood-air interspace, while most of the red cell mass is at the bottom of the tube. The clot retraction is quickly corrected (1) *in vitro*, with the dilution of blood, and (2) *in vivo*, with the reduction of the red cell mass

and the correction of the hematocrit to normal values by means of venesections. An additional mechanism in the defect of clot retraction may be the thrombocytopenia which has been observed in some of these patients.

An analytic study of the various clotting factors and of tests which give an over-all indication of the adequacy of the coagulation process supplies many interesting results, which, in the experience of the authors, may be summarized as follows: (1) decreased activity of the antihemophilic globulin (AHG) and of the plasma thromboplastic component (PTC); (2) true hypoprothrombinemia and, possibly, decreased activity of accessory factors of prothrombin conversion, (3) sharp decrease in the concentration of fibrinogen.<sup>2</sup> The patient's serum accelerates the generation of thromboplastin when added to normal platelets and plasma, thus suggesting the presence of clotting accelerator factors. There are no anticoagulants, but at least in the experience of the authors, fibrinolytic and antifibrinolytic activity are increased.

The interpretation of these findings is a moot question. They are not due to technical artefacts. There is also no evidence that deficient absorption of vitamin K is involved in the pathogenesis of the hypoprothrombinemia. As already suggested, the defective protein synthesis by an anoxic liver is a real possibility. Without minimizing this factor, the authors believe, however, that intravascular clotting, due to sludging and anoxia of the vascular wall, may be of primary importance in the pathogenesis of the hemostatic defect (as well as of the thrombotic tendency) in cyanotic congenital heart disease (Diagram 6-3). The low concentration and activity of factors leading to the formation of thrombin, the thrombocytopenia, and the evidence of activation of the fibrinolytic mechanism, at times found in these patients, could follow the occurrence of intravascular clotting. Additional evidence is the appearance of clotting accelerators in these patients' serum. Also, patients with cy-

<sup>2</sup> Such findings remain significant, even after proper correction is made for the excess of anticoagulant due to the low plasma volume, and in the case of prothrombin and accessory factors, for the low fibrinogen level, also when calcium added for the performance of the various tests is adjusted to the increased concentration of the anticoagulant.

DIAGRAM 6-3 PATHOGENETIC MECHANISMS OF THE COMBINED HEMORRHAGIC AND THROMBOTIC TENDENCY IN CYANOTIC CONGENITAL HEART DISEASE

coumarins in full doses appears contraindicated because of the hypersensitivity of these patients to such drugs,<sup>7</sup> even though they also exhibit a latent hemorrhagic tendency. Only cautious doses of Dicumarol or analogues can be considered, with careful control of the plasma prothrombin time and of possible hemorrhagic manifestations (nasal mucosa, skin, urine). Heparin may be used in standard doses, with careful control of the clotting time and frequent examination of the patient for signs of clinical bleeding.

Thrombosis, especially of the cerebral vessels, becomes of greater impact following corrective cardiac surgery, as it apparently occurs in 3 to 4 per cent of all cases (Favre-Gilly et al.) These figures are probably unrealistic, since they are based on data which were not always checked by autopsy, but they are still significant enough to indicate the magnitude of this problem. Prevention and treatment of this surgical complication present many difficulties. The thrombotic tendency of these patients, however, is well correlated with their blood viscosity. This is nearly twice as

high (9 to 11 times that of water) as in normal blood (5 to 6 times) (Isaacs).

In the experience of the authors, no operation should be attempted in these patients unless their hematocrit has been reduced to a level at which the blood viscosity is nearer to normal. Thus may not always be possible, but in any case, venesections carried out until the patient notices an increase of dyspnea have been proved to reduce the evidence of post-surgical thrombotic complications. This is a somewhat debatable point, and the individual experience of the surgeon should be the most important factor in deciding how much and how quickly blood should be removed.

The authors routinely remove two-tenths to three-tenths of the calculated blood volume in a period of a few days, at the rate of 1 pint (500 ml) a day or less, depending on the age of the patient. The volume withdrawn is replaced with freshly collected plasma. The incidence of thrombotic complications seems lessened by the use of this approach. Venesection is also followed by a rise in the platelet count, plasma fibrinogen level, and prothrombin activity, when these are low (Diagram 6-3). Thus, the hemostatic mechanism reverts to a state of relative normality as the clot retraction, number of platelets, and coagulation mechanism become adequate, while the possibility of hemorrhagic complications is reduced as well.

<sup>7</sup> The hypoxia of the liver seems accompanied by impairment of function, which may cause a relative inhibition of the synthesis of prothrombin. Such hypoxia is supported by the finding that these patients have poor BSP excretion, which reverts to normal when venesections reduce the hematocrit to near normal values. Coumarin drugs, in any case, have a more rapid, severe, and prolonged antagonistic effect in these patients.

The occurrence of thrombosis in the

hours following surgery is a serious complication. For the above reasons, coumarin drugs should be given only in small doses while heparin may be used with less circumspection, provided patient is under observation for the appearance of bleeding manifestations. Full details of anticoagulant treatment are found in Taussig's monograph (1947a).

Patients with cyanotic congenital heart disease also present a well-known *hemorrhagic tendency*, which is similar to that found in polycythemia vera and in hypoxic secondary polycythemia. The bleeding manifestations consist of epistaxis, hemoptysis, hematemesis, cerebral hemorrhages, and spreading ecchymotic areas in the skin. Their occurrence has been described as "high" by Hartman.

A clue to the mechanism of hemorrhage in these patients is the behavior of the *erythrocyte sedimentation rate*, which is very low, normally less than 5 mm/1 hr by the method of Westergren, and often as low as 0. Together with high blood viscosity and high red cell mass, other factors must be present to explain such a low erythrocyte sedimentation rate. One of these factors is the severe fibrinogenopenia of these patients.

Fibrinogen deficiency, however, is only a facet of the breakdown of the hemostatic process through a complex mechanism (Diagram 6-3). The *tourniquet test* is often positive, possibly because of the damaging effects of hypoxia on the vessel walls. The *clotting time* determined in silicone-coated test tubes may be slightly prolonged. *Clot retraction* is impaired because of a variety of causes which include fibrinogenopenia, poor production of thrombin, and low plasma with high red cell volumes. The most important factors are probably the high red cell mass and the inability of the reduced fibrinogen to hold red cells into a firm clot. Thus, the retraction of a plasma clot is adequate. When, however, whole blood is observed, the poor fibrin mesh is unable to hold on to the red cell mass. Two phenomena may then become apparent: either the clot shrinks rapidly and sinks to the bottom of the test tube, or the clot appears as a small knob at the blood-air interspace, while most of the red cell mass is at the bottom of the tube. The clot retraction is quickly corrected: (1) *in vitro*, with the dilution of blood; and (2) *in vivo*, with the reduction of the red cell mass

and the correction of the hematocrit to normal values by means of venesections. An additional mechanism in the defect of clot retraction may be the thrombocytopenia which has been observed in some of these patients.

An analytic study of the various clotting factors and of tests which give an over-all indication of the adequacy of the coagulation process supplies many interesting results, which, in the experience of the authors may be summarized as follows: (1) decreased activity of the antihemophilic globulin (AHG) and of the plasma thromboplastic component (PTC); (2) true hypoprothrombinemia and, possibly, decreased activity of accessory factors of prothrombin conversion, (3) sharp decrease in the concentration of fibrinogen.\* The patient's serum accelerates the generation of thromboplastin when added to normal platelets and plasma, thus suggesting the presence of clotting accelerator factors. There are no anticoagulants, but at least in the experience of the authors, fibrinolytic and antifibrinolytic activity are increased.

The interpretation of these findings is a moot question. They are not due to technical artefacts. There is also no evidence that deficient absorption of vitamin K is involved in the pathogenesis of the hypoprothrombinemia. Without minimizing this factor, the authors believe, however, that intravascular clotting due to sludging and anoxia of the vascular wall, may be of primary importance in the pathogenesis of the hemostatic defect (as well as of the thrombotic tendency) in cyanotic congenital heart disease (Diagram 6-3). The low concentration and activity of factors leading to the formation of thrombin, the thrombocytopenia, and the evidence of activation of the fibrinolytic mechanism, at times found in these patients, could follow the occurrence of intravascular clotting. Additional evidence is the appearance of clotting accelerators in these patients' serum. Also, patients with cy-

\* Such findings remain significant, even after proper correction is made for the excess of anticoagulant due to the low plasma volume, and in the case of prothrombin and accessory factors, for the low fibrinogen level, also when calcium added for the performance of the various tests is adjusted to the increased concentration of the anticoagulant.

notic congenital heart disease who died at surgery and showed a severe hemostatic breakdown during life present occasionally intravascular deposition, especially in the smaller pulmonary vessels, of material resembling fibrin (Beaumont and Bourgain). Finally, it has been observed that the concentration of fibrinogen and the activity of plasma prothrombin in these patients may change rapidly from day to day, possibly in relation to the extent of a process of continuous intravascular clotting.

The hemorrhagic tendency becomes of greater significance during and after surgical procedures. The tendency of these patients to bleed after dental extractions, tonsillectomies, or even minor cuts and abrasions is well known. More serious bleeding manifestations are encountered when corrective cardiac surgery is carried out. Fatal hemorrhage occurs in about 15 per cent of patients with congenital heart disease in the few days following cardiac surgery (Potts, Taussig et al., 1951). The figures are at least three times higher in the experience of European surgeons (Favre-Gilly et al.) Usually, bleeding does not occur during surgery, rather in the immediate postoperative course. The pathogenesis of such severe bleeding is not altogether clear. Of particular inter-

est in this respect is a patient (Beaumont and Bourgain) who bled fatally following the repair of an atrial septal defect with pulmonary stenosis. Blood was uncoagulable and fibrinogen level was very low; yet, at postmortem, the smaller pulmonary vessels showed both old, partly recanalized, and recent thrombi. This finding again suggested that incoagulability of the blood might have been the end result of intravascular coagulation.

The prevention of the occurrence of fatal hemorrhage in the course of, and after, corrective cardiac surgery is based on reducing the red cell mass by venesections, with or without replacement by plasma or fibrinogen. In the practice of the authors, patients with primary or secondary polycythemia who are scheduled for surgery are routinely venesected to an almost normal hematocrit and transfused with normal plasma. Hemorrhagic and thrombotic complications have become almost obsolete with this technique. The experience of the authors with cases of cyanotic congenital heart disease, unfortunately more limited, suggests the same approach. This method of preventive treatment has been fully described in the discussion of the prevention of the thrombotic accidents.

# Cardiac catheterization in congenital heart disease

ALFRED P. FISHMAN  
AND A. GREGORY JAMESON

## INTRODUCTION

Intubation of the human heart is currently accomplished by three routes: (1) venous, (2) retrograde arterial, and (3) direct cardiac. Of the three, venous catheterization of the right heart has been most extensively applied to the diagnosis of congenital heart disease (Bing, 1952; Courmand et al, 1949, 1953, Burchell et al., 1948, Dexter et al., 1947; Donzelot et al., 1954, Edwards et al., Gotzsche et al.; Keith et al.; Zimmerman), it has been used to provide (1) mixed venous blood for the calculation of cardiac output by the Fick principle, (2) blood samples for the estimation of flow through intracardiac shunts; (3) central venous sites for the injection of tracer substances for the calculation of cardiac output and central blood volume, (4) direct recordings of mechanical and electrical events, and heart sounds from within the cardiac cavities; and (5) a channel for the intracardiac injection of contrast material for the roentgen visualization of intracardiac structures and channels of flow.

It is pertinent to stress at this point that cardiac catheterization is no substitute for an adequate clinical examination. Indeed, the technique is most rewarding when preliminary examinations focus the attention of a skilled team on the types of defect which may be anticipated.

*Nature of the Defects Generally Encountered in Congenital Heart Disease.* In general,

there are four types of cardiovascular abnormalities which may be encountered by the probing catheter: (1) an abnormal communication between contiguous cardiac chambers and/or adjacent vessels, (2) a stenosis or atresia of a normal valvular communication between consecutive chambers, (3) anomalous origins or insertions of major vessels, and (4) combinations of 1, 2, and 3.

*Physiologic Basis for Evaluation of Data Obtained by Venous Catheterization.* Some aspects of the normal circulation warrant emphasis with respect to the interpretation of data obtained by cardiac catheterization in patients with congenital heart disease:

Within the first few days of life, there is functional closure of the ductus arteriosus and the foramen ovale (Born et al.); the pulmonary circulation is thereby separated from the systemic circulation. This postnatal separation of the two circulations may be demonstrated by the combination of arterial oximetry and the intravenous injection of the blue dye T 1824 (Burchell, 1950); a curve depicting the change in dye concentration at the arterial site is free of evidence for either intrapulmonary recirculation or the early entry of dye into the systemic arterial circulation.

In the normal heart, the average cardiac outputs of both sides of the heart are, under steady-state conditions, approximately equal. In the presence of intracardiac communications, valvular insufficiency, or extensive bronchial collateral circulation, this balance may

notic congenital heart disease who died at

monary vessels, of material resembling fibrin (Beaumont and Bourgain). Finally, it has been observed that the concentration of fibrinogen and the activity of plasma prothrombin in these patients may change rapidly from day to day, possibly in relation to the extent of a process of continuous intravascular clotting.

The hemorrhagic tendency becomes of greater significance during and after surgical procedures. The tendency of these patients to bleed after dental extractions, tonsillectomies, or even minor cuts and abrasions is well known. More serious bleeding manifestations are encountered when corrective cardiac surgery is carried out. Fatal hemorrhage occurs in about 1.5 per cent of patients with congenital heart disease in the few days following cardiac surgery (Potts, Taussig et al., 1951). The figures are at least three times higher in the experience of European surgeons (Favre-Gilly et al.). *Usually, bleeding does not occur during surgery; rather in the immediate postoperative course.* The pathogenesis of such severe bleeding is not altogether clear. Of particular inter-

est in this respect is a patient (Beaumont and Bourgain) who bled fatally following the repair of an atrial septal defect with pulmonary stenosis. Blood was uncoagulable and fibrinogen level was very low, yet, at postmortem, the smaller pulmonary vessels showed both old, partly recanalized, and recent thrombi. This finding again suggested that incoagulability of the blood might have been the end result of intravascular coagulation.

The prevention of the occurrence of fatal hemorrhage in the course of, and after, corrective cardiac surgery is based on reducing the red cell mass by venesections, with or without replacement by plasma or fibrinogen. In the practice of the authors, patients with primary or secondary polycythemia who are scheduled for surgery are routinely venesected to an almost normal hematocrit and transfused with normal plasma. Hemorrhagic and thrombotic complications have become almost obsolete with this technique. The experience of the authors with cases of cyanotic congenital heart disease, unfortunately more limited, suggests the same approach. This method of preventive treatment has been fully described in the discussion of the prevention of the thrombotic accidents.

TABLE 6-5. NORMAL VALUES FOR THE OXYGEN CONTENT OF BLOOD SAMPLES WITHDRAWN FROM THE CENTRAL VEINS AND RIGHT HEART

| Location                     | O <sub>2</sub> content,<br>ml 100 ml | O <sub>2</sub> saturation,*<br>per cent |
|------------------------------|--------------------------------------|---|
| Inferior vena cava           | 15.8                                 | 80                                      |
| Superior vena cava           | 15.0                                 | 76                                      |
| Right atrium; coronary sinus | 15.1                                 | 17                                      |
| Right atrium; transpulmonary | 15.3                                 | 78                                      |
| Right ventricle              | 15.5                                 | 79                                      |
| Pulmonary artery             | 15.5                                 | 79                                      |

\* Per cent oxyhemoglobin saturation as determined spectrophotometrically or calculated from Van Slyke analysis as

$$\frac{\text{O}_2 \text{ content}}{\text{O}_2 \text{ capacity}} = \frac{\text{dissolved O}_2}{\text{dissolved O}_2} \times 100$$

abnormal communication between the two circulations will establish pressure gradients for left-to-right flow. In Table 6-4 are listed representative normal values for each circulation.

The pulmonary artery pressure is little affected by large increments in pulmonary vascular flow (Courmand), acute hypoxia generally affects larger increments in pressure (5 to 10 mm Hg) with only slight increases in blood flow. Experiments with acute hypoxia in normal subjects (Fishman et al.) have emphasized the pitfalls entailed in translating a change of resistance of a vascular bed (measured as pressure drop divided by blood flow) into a change of vasomotor activity.

Pulmonary artery and right ventricular systolic pressures are virtually identical, at rest and during exercise, even with dilatation of the pulmonary artery, unless there is a narrowing which creates a gradient between them.

Each chamber and vessel has a characteristic pressure pulse, as well as pressure level. In some instances, as in the case of the left and right atria, these may be sufficiently different to be of diagnostic aid (Fig. 6-42).

If a communication is established between the two circulations, the degree of shunting will depend, in large part, on the relative sizes of both the defect and the normal channels. If the defect is sufficiently small, it may

constitute almost the entire resistance to flow, on the other hand, as it approaches the normal outlet in size, resistances distal to the defect may largely determine the degree of shunting. Thus, flow through a congenital ventricular septal defect having the same size as the aortic outlet is largely a function of the degree of stenosis of the pulmonary valve and of the anatomic alterations in the pulmonary vascular bed.

In the normal subject, the intact cardiac septa and the closed ductus arteriosus separate the arterialized blood, contained in the left heart and aorta, from the venous blood in the right heart and pulmonary artery. In the presence of an abnormal communication, the pressure gradients between adjacent structures will favor the addition of arterialized blood to venous blood unless the normal relation of pulmonary to systemic resistance has been reversed. Attempts to upset this balance physiologically, as by acute hypoxia which raises pulmonary artery pressure (Burchell et al.), are of more hemodynamic than diagnostic interest. In Table 6-5 are listed representative values for the oxygen content of blood sampled from the great veins and right heart of a normal subject, as indicated in this table, venous blood achieves complete mixing and uniform composition at the level of the right ventricle and pulmonary artery.

The comparison of the oxygen content of samples consecutively withdrawn from consecutive cardiac chambers is valid only in the face of a stable state of the respiration and circulation. In this state, the oxygen contents of each chamber remain relatively constant, in changing states, such as may occur during anesthesia or excitement, blood pressures, flows, and oxygen contents may be constantly changing, complicating not only the comparison of the oxygen content of consecutive samples but also the interpretation of oximeter blue-dye curves.

#### INFORMATION OBTAINED BY CARDIAC CATHETERIZATION

*The Course of the Catheter.* The most direct evidence for the presence of a congenital cardiac defect is the fluoroscopic demonstration of an abnormal course of the cardiac catheter (Courmand et al., 1959). This evidence may become difficult to interpret in an enlarged, abnormal heart; in such cases, aid

Fig 6-42. A. Simultaneous left ventricular (LV) and left atrial (LA) pressure pulses in a patient with normal circulation. The positive waves (a, c, v) and the negative wave (x) of the normal left atrial pressure pulse are indicated. B. Simultaneous aortic (AO) and pulmonary artery (PA) pressure pulses in a patient with normal circulation. The paper speed is 25 mm/sec on the left and 75 mm/sec on the right. Time lines are 0.04 sec apart. Arrows indicate the beginning of ejection and end of protodiastole in the aorta and pulmonary artery (Braunwald, Fishman, and Cournaud)

be upset, effecting a different volume-work load on the two ventricles.

Immediately following the physiologic closure of the ductus arteriosus, blood pressures in the pulmonary circulation approximate those in the systemic circulation. Within a few weeks, despite the continued output of equal blood volumes by both ventricles, adult blood pressure relationships are established; these are characterized by lower blood pressures in the right ventricle and pulmonary artery than in their systemic counterparts<sup>1</sup> (Table 6-4). The drop in vascular resistance and blood pressure in the pulmonary circulation is associated with the transition of prenatal thick-walled, small muscular arteries into thin-walled adult vessels (Edwards,

1953). The left atrial mean blood pressure also exceeds the right atrial mean pressure. Consequently, if the pulmonary circulation undergoes its normal postnatal evolution, an

TABLE 6-4. NORMAL BLOOD PRESSURES IN THE PULMONARY AND SYSTEMIC CIRCULATIONS

| Location          | Systolic | Diastolic, mm Hg | Mean |

<sup>1</sup> See Part 4, Chap 12, for normal data. Editor.

formed intracavitary pressure pulses; e.g., tricuspid insufficiency characteristically alters the right atrial pressure pulse (Fig. 6-44); (2) abnormal pressure gradients across valves (Fig. 6-45); (3) pressure pulses similar to those of the left heart chambers recorded during right heart catheterization (Fig. 6-46); (4) abnormal levels of intracardiac blood pressure, these have to be interpreted in the light of other observations. Thus, right ventricular systolic hypertension may reflect increased resistance to outflow posed by a stenotic pulmonic orifice, by pulmonary vascular

changes, or by free communication between the right ventricle and the systemic circulation via a large interventricular septal defect, an elevated end-diastolic pressure in the right ventricle establishes right heart failure but does not define the cause. Some characteristic values for intracardiac blood pressures in congenital heart disease are illustrated in Table 6-6.

**Intracardiac Variations in Blood Oxygen Content.** A left-to-right shunt may be recognized by detecting the admixture of arterialized blood to the venous blood traversing the

Fig. 6-44. (Upper) Pressure pulses recorded from the left atrium (LA) and right atrium (RA) prior to circumferential ligature of the atrial septal defect. The similarity in the left and right atrial pressure pulses is consistent with a large defect. The pressure pulses are distorted by high peaks which accompany functional insufficiency of the AV valves during premature ventricular beats. (Lower) Immediately following closure of the defect, the right atrium became a flaccid bag; the pressure pulse (RA) is devoid of characteristic contour. On the other hand, the contour of the left atrial pressure pulse (LA) is consistent with a functional insufficiency of the mitral valve; this insufficiency pattern is ascribable to the nodal rhythm.

in localization may be afforded by recording characteristic blood pressures and pressure pulses from the tip of the catheter. Highly specialized techniques such as intracavitary electrocardiography or phonocardiography may occasionally be of help, the role of selective angiocardiography is discussed below. X-rays

nical skill is available for reliable oximetry and for the analysis of individual blood samples and if the volume of blood required for both procedures is not excessive. A large increment in oxygenation, which persists in samples obtained from multiple sites within and distal to a chamber, suggests a large shunt. However, there are several considerations which limit the equation of an increment in oxygen content to a left-to-right shunt. (1) the observed increment must exceed analytic error and must not reflect incomplete mixing of normal converging streams, e.g., the vena cava and coronary sinus in the right atrium; (2) the respiration and circulation must be sufficiently stable so as to avoid spontaneous fluctuations in oxygen content between successive samplings, this is particularly difficult to accomplish in anesthetized patients, and (3) other types of congenital anomalies, such as insertion of pulmonary veins into the right atrium, which may be responsible for abnormal increments in oxygen content must be excluded. The latter situation is especially troublesome in the case of atrial septal defects since these are frequently associated with anomalous

insertions of pulmonary veins into the right atrium.

The possible errors mentioned under (1), above, as well as other possible errors due to sampling, handling, or analysis of the specimens, can be minimized by statistical evaluation of the analytic results, e.g., by comparison of the average values from the different chambers by the "t test." The sensitivity of the statistical result increases as the number of samples increases. Spectrophotometric methods of blood analysis permit the use of many samples without excessive blood loss, except in the smallest infants, and provide highly accurate results. Indeed, when multiple small samples from successive chambers are analyzed spectrophotometrically and the mean values are statistically compared by the "t test," the sensitivity of shunt detection is of the same order of magnitude as that obtained with the use of the test gases other than oxygen (Grayzel and Jameson, unpublished data).

Other possible sources of confusion warrant brief mention. Thus, a small atrial defect with left-to-right shunt may be missed and a ventricular septal defect may be erroneously di-

Fig. 6-46. Simultaneous left atrial (LA), right atrial (RA), and differential atrial (DIFF) pressure curves in a subject with normal circulation. Note the high V point in the left atrial pressure curve. The differential pressure curve demonstrates that the left atrial pressure exceeds the right atrial pressure virtually throughout the entire cardiac cycle. (Braunwald, Fishman, and Courmand.)

Fig. 6-45. A Characteristic pressure pulses in pulmonic valve stenosis. As the catheter is withdrawn from the pulmonary artery (PA), the low, distorted pulmonary artery pressure pulse is abruptly succeeded by a right ventricular (RV) pattern. The right ventricular systolic hypertension contrasts sharply with the level of blood pressure in the pulmonary artery.

6 Characteristic pressure pulses in subvalvular aortic stenosis. As the catheter is withdrawn from the body of the left ventricle past the subvalvular stenosis, the high systolic pressure is reduced abruptly to an abnormally low pressure in the infundibular chamber. There is no further change in the systolic pressure as the catheter is withdrawn across the aortic valve into the aorta.

C. Hydrogen curves recorded simultaneously with platinum-tipped catheters from the pulmonary artery and the brachial artery in a patient with a left-to-right shunt at the ventricular level. After the patient inhales gaseous hydrogen, the appearance of the

central systemic veins, the right heart, or the pulmonary artery. Two techniques are generally used, either singly or in combination: *cumette oximetry* for rapid estimation of oxyhemoglobin saturation of blood sampled from consecutive cardiac chambers and vessels and the more tedious determination of oxygen content or oxyhemoglobin saturation in individual blood samples by the *Van Slyke* or *spectrophotometric* methods; the latter are generally completed after the cardiac catheter has been withdrawn.

There is little question that a combination of the two is most rewarding if adequate tech-

gas in the right side of the heart sooner than in the peripheral artery signals the presence of a left-to-right shunt at or proximal to the position of the intracardiac sampling site.

han 05  
amber

(Clark and Bargeron) Similar principles govern the use of oxygen and these other test substances for the identification of a left-to-right shunt. The nitrous oxide method appears to be somewhat less sensitive than the other three. The radioactivity of the krypton and the ethyl iodide is a possible drawback to their use. The hydrogen method has the advantage of requiring no blood samples (Fig. 6-45C).

**Oxygen Unsaturation of Hemoglobin in Arterial Blood.** In unanesthetized patients with

congenital cardiac defects, systemic arterial hemoglobin unsaturation reflects the admixture of venous to arterial blood. Despite extensive pulmonary vascular lesions, diffusion limitation for oxygen apparently contributes little to the systemic arterial hypoxemia. The type of peripheral arterial unsaturation which results from venous-arterial admixture is generally not relieved by breathing 100 per cent oxygen. Localization of the site of the veno-arterial shunt generally requires methods other

C. Hydrogen curves recorded simultaneously with platinum-tipped catheters from the pulmonary artery and the brachial artery in a patient with a left-to-right shunt at the ventricular level. After the patient inhales gaseous hydrogen, the appearance of the

central systemic veins, the right heart, or the pulmonary artery. Two techniques are generally used, either singly or in combination: *cuvette oximetry* for rapid estimation of oxyhemoglobin saturation of blood sampled from consecutive cardiac chambers and vessels and the more tedious determination of oxygen content or oxyhemoglobin saturation in individual blood samples by the *Van Slyke* or *spectrophotometric methods*; the latter are generally completed after the cardiac catheter has been withdrawn.

There is little question that a combination of the two is most rewarding if adequate tech-

gas in the right side of the heart sooner than in the peripheral artery signals the presence of a left-to-right shunt at or proximal to the position of the intracardiac sampling site.

Although these formulas for pulmonary and systemic blood flow are in general use, they add little to the clinical and fluoroscopic evidence for increased or decreased pulmonary blood flow. Ridiculous values may result from inadequate sampling of mixed venous blood. The formulas also become totally inadequate in the presence of large systemic collateral flow to the lungs.

*Estimation of the Degree of Stenosis and the Size of Intracardiac Defects.* Considerable insight as to the functional significance of the stenosis of a semilunar valve may be gained from a clinical appraisal of the degree of hypertrophy and dilatation of the respective ventricle; in the case of pulmonic stenosis, this clinical evidence is supported by the demonstration of right ventricular systolic hypertension by cardiac catheterization. Cardiac catheterization may also provide some indirect evidence as to the size of a defect, thus, in the case of a left-to-right shunt, a large defect is suggested by sampling highly oxygenated blood over a wide area in a right heart chamber; this evidence for a large shunt may be supported by pulmonary hypertension and a wide pulmonary artery pulse pressure.

In the case of a right-to-left shunt, a large venoarterial communication is suggested by a considerable degree of systemic hypoxemia, the degree of venous admixture may be estimated from a simple mixing formula which calculates the volume of mixed venous blood which must be added to fully oxygenated pulmonary venous blood in order to obtain the observed peripheral arterial oxyhemoglobin saturation (Burchell, 1950). In the presence of large venoarterial shunts (greater than 27 per cent of the pulmonary blood flow), the hemoglobin of systemic arterial blood generally remains unsaturated despite the breathing of 100 per cent oxygen.

A more direct method has been developed for estimating the size of a septal defect, this entails the use of a balloon-tipped catheter which is inflated *in situ* with radiopaque material to delineate the diameter of the defect, this method has also been used to estimate the volume flow through the defect by comparing the oxygen content of blood defect, it has also been used to estimate the volume flow through the defect by comparing the oxygen content of blood sampled in the vicinity of the defect, prior to and following functional

obliteration of the abnormal communication (Kjellberg et al., 1950).

*Limitations in the Interpretation of the Results.* Although considerable information may be gained from cardiac catheterization, there are several limitations which are inherent in its application to congenital heart disease (1) the catheter may fail to enter an area of stenosis, or an abnormal communication, or an anomalous origin or insertion of a great vessel; (2) the degree of shunting may be so small as to escape detection on the basis of blood gas analyses; (3) multiple shunts or complex defects involving atrial and ventricular cavities may be difficult to identify, and (4) estimates of blood flow through the pulmonary circulation may, in the face of intracardiac shunts, be totally erroneous. These deficiencies may generally be overcome by appropriate use of complementary diagnostic methods.

## ATRIAL SEPTAL DEFECT

The presence of an atrial septal defect may be identified by introducing the catheter into the left atrium during right heart catheterization (Cournand et al., 1949, 1953). If such a defect is suspected prior to catheterization, it may be desirable, particularly in children, to catheterize a vein of the lower, rather than the upper, extremity, since traversal of an atrial septal defect is apparently facilitated by entering the heart via the venous stream from below (Lind and Wegelius). However, this gain in approach to the atrial defect sacrifices the ease in entering the pulmonary artery via an upper extremity route.

The entry of the catheter into the left atrium may be established by (1) further advancing the catheter into a pulmonary vein or the left ventricle, (2) recording typical left atrial pressure pulses, and (3) withdrawing blood samples which are enriched in oxygen content as compared to samples drawn from the venae cavae.

The sampling of arterialized blood from the right atrium does not identify an atrial septal defect. Similar samples may be obtained when there is anomalous insertion of pulmonary veins into the right atrium, distinction between these two anomalies is complicated by the frequent association of atrial septal defects with anomalous insertions of the pulmonary veins. Other causes for arterialization of right atrial

agnosed if the oxygenated stream is first encountered in the right ventricle, a ventricular septal defect may also be suggested by the regurgitation of oxygenated blood through an insufficient pulmonary valve in a patient with a patent ductus arteriosus and pulmonary hypertension. Finally, the incorrect diagnosis of patent ductus arteriosus may be proposed on the basis of oxygenated blood withdrawn

from a catheter advanced almost to a wedge position.

*The Use of Test Gases Other than Oxygen for the Detection of Left-to-Right Shunts.* Recent work to improve the sensitivity and speed of shunt detection has led to the introduction of four inhalants, nitrous oxide (Morrow), radioactive krypton (Sanders), radioactive ethyl iodide (Case et al), and hydrogen

**TABLE 6-6. REPRESENTATIVE DATA OBTAINED BY CARDIAC CATHETERIZATION IN CONGENITAL HEART DISEASE**

|                                 | Diagnostic location of catheter | Blood pressure          |  |                                   | Blood samples          |                         |  |
|---------------------------------|---------------------------------|-------------------------|--|-----------------------------------|------------------------|-------------------------|--|

| Small ventricular septal defect | Left ventricle and aorta        | .                       | ..   | ...                               | Exceeds right atrium   |                         |  |
| Patent ductus arteriosus        | Aorta                           | .                       | ...  | .                                 | ...                    | Exceeds right ventricle |  |

Although these formulas for pulmonary and systemic blood flow are in general use, they add little to the clinical and fluoroscopic evidence for increased or decreased pulmonary blood flow. Ridiculous values may result from inadequate sampling of mixed venous blood. The formulas also become totally inadequate in the presence of large systemic collateral flow to the lungs.

*Estimation of the Degree of Stenosis and the Size of Intracardiac Defects.* Considerable insight as to the functional significance of the stenosis of a semilunar valve may be gained from a clinical appraisal of the degree of hypertrophy and dilatation of the respective ventricle; in the case of pulmonic stenosis, this clinical evidence is supported by the demonstration of right ventricular systolic hypertension by cardiac catheterization. Cardiac catheterization may also provide some indirect evidence as to the size of a defect, thus, in the case of a left-to-right shunt, a large defect is suggested by sampling highly oxygenated blood over a wide area in a right heart chamber; this evidence for a large shunt may be supported by pulmonary hypertension and a wide pulmonary artery pulse pressure.

In the case of a right-to-left shunt, a large venoarterial communication is suggested by a considerable degree of systemic hypoxemia, the degree of venous admixture may be estimated from a simple mixing formula which calculates the volume of mixed venous blood which must be added to fully oxygenated pulmonary venous blood in order to obtain the observed peripheral arterial oxyhemoglobin saturation (Burchell, 1950). In the presence of large venoarterial shunts (greater than 27 per cent of the pulmonary blood flow), the hemoglobin of systemic arterial blood generally remains unsaturated despite the breathing of 100 per cent oxygen.

A more direct method has been developed for estimating the size of a septal defect, this entails the use of a balloon-tipped catheter which is inflated *in situ* with radiopaque material to delineate the diameter of the defect, this method has also been used to estimate the volume flow through the defect by comparing the oxygen content of blood defect, it has also been used to estimate the volume flow through the defect by comparing the oxygen content of blood sampled in the vicinity of the defect, prior to and following functional

obliteration of the abnormal communication (Kjellberg et al., 1950).

*Limitations in the Interpretation of the Results.* Although considerable information may be gained from cardiac catheterization, there are several limitations which are inherent in its application to congenital heart disease: (1) the catheter may fail to enter an area of stenosis, or an abnormal communication, or an anomalous origin or insertion of a great vessel, (2) the degree of shunting may be so small as to escape detection on the basis of blood gas analyses; (3) multiple shunts or complex defects involving atrial and ventricular cavities may be difficult to identify, and (4) estimates of blood flow through the pulmonary circulation may, in the face of intracardiac shunts, be totally erroneous. These deficiencies may generally be overcome by appropriate use of complementary diagnostic methods.

### ATRIAL SEPTAL DEFECT

The presence of an atrial septal defect may be identified by introducing the catheter into the left atrium during right heart catheterization (Courmand et al., 1949, 1953). If such a defect is suspected prior to catheterization, it may be desirable, particularly in children, to catheterize a vein of the lower, rather than the upper, extremity, since traversal of an atrial septal defect is apparently facilitated by entering the heart via the venous stream from below (Lind and Wegelius). However, this gain in approach to the atrial defect sacrifices the ease in entering the pulmonary artery via an upper extremity route.

The entry of the catheter into the left atrium may be established by (1) further advancing the catheter into a pulmonary vein or the left ventricle, (2) recording typical left atrial pressure pulses, and (3) withdrawing blood samples which are enriched in oxygen content as compared to samples drawn from the venae cavae.

The sampling of arterialized blood from the right atrium does not identify an atrial septal defect. Similar samples may be obtained when there is anomalous insertion of pulmonary veins into the right atrium, distinction between these two anomalies is complicated by the frequent association of atrial septal defects with anomalous insertions of the pulmonary veins. Other causes for arterialization of right atrial

than cardiac catheterization, such as angiography or the combination of cardiac catheterization and other specialized techniques, such as multiple injections of test substances at various sites within the heart. Arterial unsaturation of one segment of the body may be of diagnostic value, thus, in a patent ductus arteriosus with reversal of flow, greater unsaturation of femoral than the right brachial artery blood generally occurs.

**The Venous Injection of Dye Combined with Arterial Oximetry.** This procedure has most value in right-to-left shunts which are identified by short appearance times and abnormal initial deflections (Wood, 1953, Burchell, 1950). Two types of additional information may be obtained: (1) localization of the site of the defect, this involves the sequential injection of dye into consecutive cardiac chambers, and (2) an estimate of the partition of blood flow between the normal and abnormal routes.

The combination of venous injection of dye and arterial oximetry is also of value in establishing the existence of a left-to-right shunt; its particular value in identifying the anomalous insertions of pulmonary veins will be discussed

later. When the Fick method is used, this entails the simultaneous measurement, in a steady state (Fishman et al.), of the oxygen uptake at the mouth in conjunction with the corresponding arterial-mixed venous blood oxygen difference. For the calculation of pulmonary blood flow in the face of a left-to-right shunt, blood is assumed to be completely mixed in the chamber distal to the site of communication, and the hemoglobin in pulmonary venous blood is assumed to be fully, or almost fully, saturated with oxygen. The following simple formulas are commonly used for the estimation of the relative blood flows through the pulmonary and systemic circulations and through the abnormal communications (Bing).<sup>2</sup>

Systemic flow (ml/min)

$$= \frac{O_2 \text{ uptake (ml/min)} \times 100}{\left\{ \begin{array}{l} O_2 \text{ content of peripheral arterial} \\ \text{blood (ml/100 ml)} \\ - \left\{ \begin{array}{l} O_2 \text{ content of mixed venous} \\ \text{blood (ml/100 ml)} \end{array} \right\} \end{array} \right\}}$$

Pulmonary artery flow (ml/min)

$$= \frac{O_2 \text{ uptake (ml/min)} + 100}{\left\{ \begin{array}{l} O_2 \text{ content of pulmonary vein} \\ \text{blood (ml/100 ml)} \\ - \left\{ \begin{array}{l} O_2 \text{ content of pulmonary artery} \\ \text{blood (ml/100 ml)} \end{array} \right\} \end{array} \right\}}$$

Effective pulmonary flow (ml/min)

$$= \frac{O_2 \text{ uptake (ml/min)} \times 100}{\left\{ \begin{array}{l} O_2 \text{ content of pulmonary vein} \\ \text{blood (ml/100 ml)} \\ - \left\{ \begin{array}{l} O_2 \text{ content of mixed venous} \\ \text{blood (ml/100 ml)} \end{array} \right\} \end{array} \right\}}$$

Over-all shunt (left to right) = pulmonary artery flow - systemic flow

Over-all shunt (right to left) = systemic flow - pulmonary artery flow

Total left-to-right shunt = pulmonary capillary flow - effective pulmonary flow

Total right-to-left shunt = systemic flow - effective pulmonary flow

In these formulas, effective pulmonary blood flow represents the volume of blood which, after returning to the right atrium, reaches the pulmonary capillaries

usually in oxyhemoglobin saturation which are involved in the use of T-1824

**Selective Angiocardiography.** This technique involves the rapid introduction of radiopaque material into the heart through the cardiac catheter for demonstration of intracardiac structures and patterns of blood flow (Kjellberg et al., 1950). It is particularly valuable for delineating venoarterial communications and for accurate definition of the site and nature of a cardiac defect. The procedure entails some hazard, particularly in cyanotic patients and in patients who are given multiple injections, it also requires specialized equipment for its performance. Since the information obtained depends on the site of injection of the contrast material, some preliminary screening is necessary for most fruitful yield from this technique

**Relative Blood Flows through the Pulmonary and Systemic Circulations.** In the absence of an abnormal communication, blood flow through the lungs and systemic circulation is approximately equal and may be esti-

more than a few millimeters of mercury in a patient with left-to-right atrial shunt would suggest organic pulmonic stenosis. However, the use of the pressure gradient for the estimation of the degree of stenosis is handicapped by the abnormally high transvalvular flows.

When an atrial septal defect is associated with mitral stenosis, it may be possible to introduce the catheter into the left ventricle in order to demonstrate a diastolic pressure gradient across the mitral valve.

### VENTRICULAR SEPTAL DEFECT

Cardiac catheterization generally clinches the clinical diagnosis of a ventricular septal defect and provides an index of its hemodynamic significance.

The most certain evidence for a ventricular septal defect is the introduction of the catheter from the right into the left ventricle or aorta; the fluoroscopic and x-ray evidence (Fig. 6-43) is then reinforced by obtaining samples of highly oxygenated blood from the tip of the catheter and by recording the transition from the high (left ventricular) to the lower (right ventricular) pressures as the catheter is withdrawn.

The catheter frequently fails to enter the left heart or aorta. However, the withdrawal of highly oxygenated blood samples from the right ventricle coupled with the clinical and electrocardiographic data are usually sufficient to establish the diagnosis. Only on rare occasions is it necessary to resort to additional techniques such as elective angiocardiography or the demonstration of abnormally brief circulation times for dye injected into the right ventricle.

An increase in oxygenation in the right ventricle must be interpreted in the light of clinical data; thus, similar increments may be caused by laminar flow from an atrial septal defect, a perforated aneurysm of the sinus of Valsalva, or pulmonary insufficiency in association with a patent ductus arteriosus and pulmonary hypertension. Exceedingly small defects may escape detection if they fail to provide a significant increase in oxygenation of right ventricular blood or if they establish a right ventricular stream which is not sampled by the catheter.

Cardiac catheterization may also provide some insight as to the size of the defect. A defect smaller than the pulmonary valve ori-

fice does not interfere with the functional separation of the two ventricles; the normal difference between right and left ventricular systolic blood pressures is therefore maintained. In the absence of pulmonic stenosis, the presence of a higher blood pressure in the right ventricle than in the systemic circulation suggests the combination of (1) a small ventricular septal defect, (2) a greater resistance to flow in the lesser circulation than in the systemic circulation, and (3) the absence of an overriding aorta.

A large defect equalizes blood pressure in both ventricles. In this circumstance, the partition of flow between systemic and pulmonary circulations depends upon the relative resistance to outflow posed by the two circulations; adequate perfusion of systemic structures may be accomplished at the expense of a decreased pulmonary blood flow if there is stenosis of the outflow tract of the right ventricle or if there are anatomic alterations in the pulmonary vascular bed. In the face of a fixed anatomic resistance in the lesser circulation, transient increases in the right-to-left flow may be accomplished by systemic vasodilator agents.

Pulmonary and right ventricular systolic and diastolic hypertension may accompany a ventricular septal defect, particularly in children. However, systemic hypoxemia due to a right-to-left shunt does not occur until systolic blood pressure in the pulmonary artery exceeds that in the systemic arteries.

A high septal defect allows passage from the right ventricle into the aorta, consequently, the entry of the catheter into the aorta from the right ventricle fails to distinguish between a high septal defect and an overriding aorta.

Such considerations have led some investigators (Selzer, Selzer and Laqueur, Becu et al.) to regard Eisenmenger's complex as a physiologic variant of a large ventricular septal defect, without pulmonic stenosis. The gradual evolution of persistent cyanosis is then ascribable to a progressive increase in pulmonary vascular resistance to blood flow, which ultimately leads to a right-to-left ventricular shunt. This explanation is consistent with the concept that the pulmonary vascular lesions of Eisenmenger's complex represent an anatomic response to increased vascular blood flow and pressures rather than a congenital abnormality of blood vessels. It also implies

and afford an index of its severity; (2) localize the site of the obstruction, i.e., valvular, infundibular, or both, and (3) establish the co-existence of other congenital anomalies.

The hallmark of pulmonic stenosis is a *systolic pressure gradient between right ventricle and pulmonary artery*. Some insight into the site and anatomic nature of the stenosis may be gained from a correlation of the distance traversed by the catheter and the nature of the pressure pulses. Thus, an abrupt change in blood pressure level and contour as the catheter crosses the pulmonic valve suggests a valvular stenosis. Figure 6-45 demonstrates systolic hypertension in the right ventricle, a distorted, damped hypotensive blood pressure in the pulmonary artery, and a sharp zone of transition between the two chambers.

By way of contrast, an example of infundibular stenosis is illustrated in Fig. 6-47. The record displays a series of intermediate complexes which persisted over the length of the right ventricular outflow tract during withdrawal of the catheter. These intermediate complexes have systolic pressure peaks equal to those in the pulmonary artery, whereas the diastolic pressures correspond to those in the right ventricle. In other instances of infundibular stenosis (Bouchard and Cornu), the intermediate complexes may be distorted by systolic dips to subzero levels, these distortions have been ascribed to *venturi effects* elicited by jets of blood through the stenotic area during ventricular ejection. Particular emphasis is generally placed on the shape of the distorted pulmonary artery pressure pulse in identifying pulmonic stenosis. On rare occasions, despite severe stenosis, a normal pulmonary artery pressure pulse has been recorded (Fig. 6-47). In this instance, the preservation of nor-

mal contour and blood pressure is probably related to an augmented pulmonary vascular flow occasioned by an associated left-to-right shunt.

These criteria, based on analysis of blood pressure records, generally suffice to identify the nature of the stenosis. Occasionally, particularly in the case of complex anomalies, they may be misleading. Thus, venturi distortions have also been recorded from an infundibular chamber (Torner-Soler et al). Moreover, in the case of combined valvular and infundibular stenosis (Fig. 6-48), the infundibular pattern may emerge only after the valvular stenosis has been surgically relieved.

Cardiac catheterization also provides an objective index of surgical accomplishment (Milstein and Brock, Kirklin et al) (Fig. 6-49). In general, a surgical attack upon the pulmonic valve decreases right ventricular systolic pressure and increases pulmonary artery pressures, but only rarely is the systolic pressure gradient between right ventricle and pulmonary artery completely abolished. It has recently been demonstrated that improvement in the blood pressures and pressure pulses may continue long (i.e., months to a year) after surgery (Himmelsstein et al.); this has been interpreted as a reflection of a gradual diminution in the subvalvular muscle mass after relief of the obstruction to right ventricular outflow. On occasion, a pulmonary insufficiency pattern may appear (Fig. 6-50).

Despite severe stenosis, pulmonary blood flow may be normal at rest and during exercise. A change in transvalvular flow may affect the pressure drop across the stenotic area. Thus, a decrease in cardiac output may diminish, whereas an increase in cardiac output may augment, the gradient. In practice, it has

Fig. 6-47. Withdrawal of the cardiac catheter from the pulmonary artery (PA) into the right ventricle (RV) in a patient with combined infundibular stenosis and atrial septal defect. The transitional complexes are characterized by systolic blood pressures equal to those in the pulmonary artery and diastolic blood pressures equal to those in the right ventricle. The normal pulmonary artery pressure pulses are discussed in the text. (From unpublished data of Himmelsstein, Jameson, Humphreys, and Fishman.)

that the degree of aortic overriding is only of minor hemodynamic significance.

### SINGLE VENTRICLE

The course of the catheter may demonstrate the origin of the aorta and pulmonary artery from a common ventricular chamber. The ventricular blood pressures and the oxygen content of blood samples are consistent with a large ventricular septal defect, the oxygen content of blood samples from the ventricle is far in excess of those drawn from the right atrium.

Associated malformations of the great vessels and of the AV valves may complicate interpretation of data obtained during cardiac catheterization. A rudimentary outlet chamber may

unless the mouth of the other vessel is stenosed. Considerable insight into the nature of the associated defects may be gained from selective angiocardiography.

### PATENT DUCTUS ARTERIOSUS

In the majority of children and young adults, clinical evidence is sufficient to establish the diagnosis of a patent ductus arteriosus. Cardiac catheterization has its greatest value in patients with atypical murmurs. Two types of supportive evidence are frequently adduced during cardiac catheterization. (1) the venous catheter may identify the ductus arteriosus by entering the channel between the left pulmonary artery and the aorta, (2) blood samples drawn from the pulmonary artery have a higher oxygen content than do samples from the right ventricle.

The distinction between a patent ductus arteriosus and an aortopulmonary septal defect is of surgical interest. Cardiac catheterization may be of some help in this regard if particular attention is paid to the course of the catheter, thus, the passage of the catheter along the aortic arch, or its entry, without angulation, into the right common carotid artery suggests an aortopulmonary septal defect rather than a patent ductus arteriosus.

In some patients, particularly those with large communications, pulmonary artery hypertension develops (Hultgren et al.; Storsten and Helle). In these subjects, pulmonary vascular resistance may continue to increase, and pulmonary artery blood pressures may equal

or even exceed systemic artery pressures (Fig. 8-51). The left-to-right shunt is then reversed and venous blood flows from the pulmonary artery into the aorta, causing peripheral arterial oxyhemoglobin unsaturation. In the case of identical pressures in both circulations, with virtually no flow across the ductus, the balance may be upset by decreasing systemic vascular resistance. This may be accomplished in a variety of ways (Burchell et al., 1948), including exercise and inhalation of amyl nitrite; the reversal of flow is then revealed by systemic oxyhemoglobin unsaturation. When reversal of flow is established, the dye-dilution curve of a left-to-right shunt is replaced by the characteristic double-humped contour of a right-to-left shunt. Of considerable diagnostic value at this time is the comparison of the oxygen content in blood samples simultaneously drawn from the femoral and right brachial arteries. In the presence of a patent ductus arteriosus with right-to-left shunt, the femoral arterial blood sample may be less saturated with oxygen than the brachial. The anatomic basis for this difference is illustrated in Fig. 8-52. This difference is another basis for distinction from an aortopulmonary window with right-to-left shunt.

Since the abnormal communication is usually not traversed by the catheter, the supportive evidence for a patent ductus arteriosus often resolves into differences between the oxygen content of blood samples successively drawn from the right ventricle and pulmonary artery. This criterion may fail to distinguish between a high ventricular septal defect and a combination of patent ductus arteriosus with left-to-right shunt, pulmonary hypertension, and pulmonary insufficiency. Conversely, a high ventricular septal defect with laminar flow of oxygenated blood into the pulmonary artery may lead to the erroneous diagnosis of a patent ductus arteriosus. In such troublesome cases, selective angiography or retrograde aortography may become necessary for identification of the anomaly.

### PULMONIC STENOSIS

Cardiac catheterization may provide several types of information with respect to pulmonic stenosis (Dow et al., 1950; Green et al.; Maraist et al.; Pollack et al.; Silber et al.). It may (1) identify the presence of an obstruction to outflow from the right ventricle

## BEFORE VALVULOTOMY

## AFTER VALVULOTOMY

Fig. 6-50. The effect of valvulotomy and extensive resection of the infundibular area in a patient with pulmonic stenosis. The operation has accomplished a striking reduction in right ventricular (RV) systolic blood pressure. Pulmonary artery (PA) systolic blood pressure has returned to normal. The identical diastolic blood pressures in the right ventricle and pulmonary artery indicate pulmonary insufficiency. (From unpublished data of Himmelstein, Jameson, Humphreys, and Fishman)

possible mechanism for such a gradient is an abnormally large transvalvular blood flow, as may occur in a left-to-right shunt. However, theoretical considerations suggest that the pressure differences required to move large volumes of blood across a normal pulmonary valve are exceedingly small, this concept is supported by the absence of measurable differences between right ventricular and pulmonary

artery systolic pressures either during severe exercise (cardiac output two to three times normal) or in hyperkinetic disease states associated with large volume flows.

Considerations such as these suggest that a systolic pressure gradient greater than a few millimeters of mercury reflects organic pulmonic stenosis, as a practical measure, to allow for artefacts in blood pressure recording

Fig. 6-51. Simultaneous blood pressures in the right ventricle and aorta in a patient with patent ductus arteriosus and reversal of flow. Records taken at the time of operation by direct puncture.

Prior to closure of the ductus, pulmonary artery systolic blood pressure exceeds the aortic. Following occlusion, the right ventricular systolic blood pressure increases further and aortic blood pressures drop as the flow of blood into the aorta via the ductus is interrupted. By 45 sec, right ventricular diastolic blood pressures have increased considerably, reflecting the onset of right heart failure. These changes promptly were reversed when the occluding ligature was released. (From unpublished observations of Jameson, Sirak, Humphreys, and Fishman)

that the degree of aortic overriding is only of minor hemodynamic significance.

### SINGLE VENTRICLE

The course of the catheter may demonstrate the origin of the aorta and pulmonary artery from a common ventricular chamber. The ventricular blood pressures and the oxygen content of blood samples are consistent with a large ventricular septal defect, the oxygen content of blood samples from the ventricle is far in excess of those drawn from the right atrium.

Associated malformations of the great vessels and of the AV valves may complicate interpretation of data obtained during cardiac catheterization. A rudimentary outlet chamber may give origin to the aorta, or pulmonary artery, or both. In general, the vessel originating from the rudimentary chamber has the lower blood flow unless the mouth of the other vessel is stenosed. Considerable insight into the nature of the associated defects may be gained from selective angiocardiography.

### PATENT DUCTUS ARTERIOSUS

In the majority of children and young adults, clinical evidence is sufficient to establish the diagnosis of a patent ductus arteriosus. Cardiac catheterization has its greatest value in patients with atypical murmurs. Two types of supportive evidence are frequently adduced during cardiac catheterization (1) the venous catheter may identify the ductus arteriosus by entering the channel between the left pulmonary artery and the aorta, (2) blood samples drawn from the pulmonary artery have a higher oxygen content than do samples from the right ventricle.

The distinction between a patent ductus arteriosus and an aortopulmonary septal defect is of surgical interest. Cardiac catheterization may be of some help in this regard if particular attention is paid to the course of the catheter, thus, the passage of the catheter along the aortic arch, or its entry, without angulation, into the right common carotid artery suggests an aortopulmonary septal defect rather than a patent ductus arteriosus.

In some patients, particularly those with large communications, pulmonary artery hypertension develops (Hultgren et al.; Storstein and Helle). In these subjects, pulmonary vascular resistance may continue to increase, and pulmonary artery blood pressures may equal

or even exceed systemic artery pressures (Fig. 6-51). The left-to-right shunt is then reversed and venous blood flows from the pulmonary artery into the aorta, causing peripheral arterial oxyhemoglobin unsaturation. In the case of identical pressures in both circulations, with virtually no flow across the ductus, the balance may be upset by decreasing systemic vascular resistance. This may be accomplished in a variety of ways (Burchell et al., 1948), including exercise and inhalation of amyl nitrite; the reversal of flow is then revealed by systemic oxyhemoglobin unsaturation. When reversal of flow is established, the dye-dilution curve of a left-to-right shunt is replaced by the characteristic double-humped contour of a right-to-left shunt. Of considerable diagnostic value at this time is the comparison of the oxygen content in blood samples simultaneously drawn from the femoral and right brachial arteries. In the presence of a patent ductus arteriosus with right-to-left shunt, the femoral arterial blood sample may be less saturated with oxygen than the brachial. The anatomic basis for this difference is illustrated in Fig. 6-52. This difference is another basis for distinction from an aortopulmonary window with right-to-left shunt.

Since the abnormal communication is usually not traversed by the catheter, the supportive evidence for a patent ductus arteriosus often resolves into differences between the oxygen content of blood samples successively drawn from the right ventricle and pulmonary artery. This criterion may fail to distinguish between a high ventricular septal defect and a combination of patent ductus arteriosus with left-to-right shunt, pulmonary hypertension, and pulmonary insufficiency. Conversely, a high ventricular septal defect with laminar flow of oxygenated blood into the pulmonary artery may lead to the erroneous diagnosis of a patent ductus arteriosus. In such troublesome cases, selective angiography or retrograde aortography may become necessary for identification of the anomaly.

### PULMONIC STENOSIS

Cardiac catheterization may provide several types of information with respect to pulmonic stenosis (Dow et al., 1930; Green et al.; Macraist et al.; Pollack et al.; Silber et al.). It may (1) identify the presence of an obstruction to outflow from the right ventricle

tricle may not be encountered. The resistance to outflow imposed by the pulmonic valve is fixed, whereas resistance to flow through the systemic circulation is determined by the state of the systemic arterioles; consequently, the balance of ventricular pressures may be upset by systemic vasodilatation, resulting in an augmentation of the right-to-left shunt and an exaggeration of systemic hypoxemia (Hamilton et al., 1950).

Various indices have been used to estimate the degree of dextroposition of the aorta. The course of the catheter is of little help since a high ventricular defect permits entry into the aorta even if there is no measurable degree of overriding. Other tests, such as the demonstration of abbreviated right-ventricle-to-ear circulation times, are unreliable. The most clear-cut demonstration of the origin of the aorta is by selective angiocardiology (Kjellberg et al., 1955).

The estimation of the volume of pulmonary blood flow by the Fick principle is particularly unreliable in this anomaly since (1) shunts complicate the sampling of mixed venous blood, and (2) the pulmonary capillaries may be perfused by systemic arterial blood as well as by pulmonary artery blood. Generally, an estimate of the ratio of systemic to pulmonary blood flow is attempted by the following type of calculations.

Systemic blood flow

$$= \frac{\text{oxygen uptake (ml/min)} \times 100}{\left\{ \begin{array}{l} \text{systemic artery } O_2 \text{ content (ml/100 ml)} \\ - \text{right atrial } O_2 \text{ content (ml/100 ml)} \end{array} \right\}}$$

Maximum pulmonary blood flow

$$= \frac{\text{oxygen uptake (ml/min)} \times 100}{\left\{ \begin{array}{l} \text{pulmonary venous } O_2 \text{ content (ml/100 ml)} \\ - \text{systemic artery } O_2 \text{ content (ml/100 ml)} \end{array} \right\}}$$

Minimum pulmonary blood flow

$$= \frac{\text{oxygen uptake (ml/min)} \times 100}{\left\{ \begin{array}{l} \text{pulmonary venous } O_2 \text{ content (ml/100 ml)} \\ - \text{pulmonary artery } O_2 \text{ content (ml/100 ml)} \end{array} \right\}}$$

Pulmonic stenosis and an atrial septal defect may mimic a tetralogy of Fallot. Selective angiocardiology has been found particularly useful in distinguishing between these combinations of defects (Kjellberg et al., 1955). On the other hand, the association of an atrial septal defect and the tetralogy of Fallot is not

uncommon (Esclavissat et al.). The atrial defect may consist only of a patent foramen ovale which is accidentally traversed by the catheter or may be sufficiently large to constitute a source of a large right-to-left shunt when right atrial pressures increase.

## ANOMALOUS INSERTIONS OF PULMONARY VEINS

*Partial Anomalous Drainage.* The diagnosis of anomalous drainage of pulmonary veins into a central systemic vein may be established from the route traversed by the catheter during central venous catheterization; it may be confirmed by demonstrating arterialized blood at the site of insertion of the anomalous vessels into the systemic veins. Cardiac catheterization may be similarly rewarding when a pulmonary vein inserts into the right atrium, particularly in the case of a vein from the right lung (Hickie). However, an erroneous diagnosis may stem from the inadvertent passage of the catheter across an atrial septal defect into the mouth of a pulmonary vein as it inserts normally into the left atrium.

Once the presence of anomalous pulmonary vein has been established, it is of surgical interest to determine whether there is an associated atrial septal defect. This problem may not be easy to resolve by cardiac catheterization unless the course of the catheter fortuitously identifies both abnormalities, the oxygen contents of blood samples from the right atrium are of no avail in this regard; nor are hemodynamic measurements of diagnostic aid since each defect alone (as well as both together) increases pulmonary blood flow and may increase pulmonary artery pressures.

In some instances, insight as to the functional significance and anatomy of anomalously inserted pulmonary veins, either alone or in combination with an atrial defect, may be gained from the nature of the curves recorded by arterial oximetry following injection of a dye into successive cardiac chambers. Occasionally, when there is a fortunate anatomic circumstance of completely normal drainage from one lung combined with completely abnormal drainage from the other, the separate injection of blue dye into each pulmonary artery may identify the abnormality. Unfortunately, the dye-dilution method is least rewarding in the usual types of anomalous insertion, as well as in the frequent combination of anomalous pul-

Fig 6-48 Withdrawal of the catheter from the pulmonary artery (PA) into the right ventricle (RV) in a patient with combined valvular and infundibular stenosis. Before valvulotomy, the pattern is characteristic of valvular stenosis. After valvulotomy, the pattern of infundibular stenosis emerges (From unpublished data of Himmelstein, Jameson, Humphreys, and Fishman)

been established that a wide gradient, measured under the usual conditions of cardiac catheterization, reflects a hemodynamically significant degree of pulmonic stenosis. Moreover, it appears that such a gradient is not obscured by the alterations in respiration and

circulation which attend anesthesia and surgical manipulation prior to the attack on the pulmonic valve (Himmelstein et al.).

The question has been repeatedly posed as to whether a systolic pressure gradient may occur without organic pulmonic stenosis; one

Fig 6-49. The effect of valvulotomy on right heart and systemic blood pressures in a patient with pulmonary valvular stenosis. The blood pressures were recorded by needle puncture prior to, and following, valvulotomy. Each record displays the ECG, the aortic (AO), right ventricular (RV), and pulmonary artery (PA) pressure pulses. Valvulotomy has reduced, but has not completely abolished, the systolic pressure gradient across the pulmonic valve. The ECG has reverted to normal (From unpublished data of Himmelstein, Jameson, Humphreys, and Fishman)

hypertension and an elevated pulmonary "wedge" pressure may reflect left heart failure.

*Arterial catheterization* reveals a characteristic distortion of the pressure pulse as the catheter traverses the stenotic area. Injection of contrast medium proximal to the stenotic area may outline the area of stenosis.

### PRIMARY PULMONARY HYPERTENSION

The value of cardiac catheterization lies in (1) establishing the existence and degree of pulmonary hypertension and (2) excluding congenital heart disease and back pressure from the left heart as its basis. The effect of ganglionic blocking agents in lowering pressures in the pulmonary circulation is of physiologic interest but of no diagnostic value.

### CORRECTED TRANSPOSITION OF THE GREAT VESSELS

Catheterization may be of help in the diagnosis of corrected transposition. Because of the altered anatomy, the catheter may take an intracardiac course suggestive of the diagnosis. The abnormal positions and relations of the atrioventricular and semilunar valves account for the unusual intracardiac courses that may be taken by the catheter. A malformation of the left atrioventricular valve, such as that seen in Ebstein's disease, is not rare (Schiebler et al.).

Pressures in the right heart in a patient without septal defect or valvular deformity studied by one of the authors (A.G.J.) were entirely normal. This observation emphasizes the point that by itself the anomaly of corrected transposition does not produce significantly altered hemodynamics. With associated defects, pressures and shunts are compatible with the associated anomalies and their severity.

Selective angiocardiology offers the most help in making the diagnosis.

### TRANSPOSITION OF GREAT VESSELS

*Complete Transposition.* Cardiac catheterization generally contributes little to the diagnosis of complete transposition of the great vessels (Campbell and Suzman). To be of diagnostic value, the catheter should enter all four cardiac chambers for the recording of blood pressures and the withdrawal of blood samples. In practice, this feat is exceedingly difficult to accomplish. Most often the catheter

is advanced from the right ventricle into the aorta, establishing from its course that the aorta arises anteriorly in the position usually occupied by the pulmonary artery (Gotsche).

Cardiac catheterization is of most value in identifying the nature and direction of flow in coexisting shunts. This estimation of the degree of shunting is generally based on variation in the oxygen content of blood samples withdrawn from successive cardiac chambers. Unfortunately, the interpretation of the degree of shunting from these data is usually complicated by apparently unpredictable variations in the magnitude, and even direction, of shunt.

*Incomplete Transposition.* In incomplete transposition of the great vessels (Taussig-Bing complex), cardiac catheterization may be more definitive (Taussig and Bing; Martin and Lewis). The catheter may enter both the aorta and pulmonary artery from the right ventricle. Because of the high ventricular septal defect, systolic pressures of both ventricles as well as both great vessels are identical. Systemic hypoxemia is generally marked, and considerable diagnostic value has been ascribed to the greater degree of oxygenation of blood in the pulmonary artery than in a systemic artery. Pulmonary blood flow is increased except in the case of associated pulmonic stenosis. Selective angiocardiology offers considerable promise in defining the origin of the great vessels as well as the nature of the associated anomalies (Kjellberg et al.).

### ENDOCARDIAL FIBROELASTOSIS

The pressure pulses in the right ventricle and atrium may resemble those of constrictive pericarditis (Fig. 6-53) due to decreased diastolic expansion of the ventricles imposed, in this instance, by a constrictive endocardial sclerosis (McKusick and Cochran). In practice, particularly in infants and children, this distinctive pattern is generally not manifest.<sup>2</sup>

### AORTIC STENOSIS

Surgical attack on aortic stenosis is now common. It is desirable in planning operation to know the nature and severity of the obstruction. Except for the difference in the site of obstruction, there appears to be no significant clinical or hemodynamic difference between the

<sup>2</sup> See also special chapter for this topic: Part 16, Chap. 12, Editor.

and "catheter whip," a gradient in excess of 10 to 15 mm Hg may generally be accepted as evidence of organic pulmonic stenosis. Moreover, in the case of complex anomalies, in which there are alternate routes for egress of blood from the right heart, even a small transpulmonary gradient may reflect severe pulmonic stenosis, if the balance of outflow resistances is such as to deviate blood away from the fixed high resistance at the pulmonary valve area.

The end-diastolic pressure in the right ventricle may remain normal despite systolic blood pressures in excess of 200 mm Hg, an increase in end-diastolic pressure above 5 to 7 mm Hg, in a resting subject, is generally associated with systemic evidence of right heart failure. Incipient failure of the ventricle may be demonstrable only by an elevation of the end-diastolic pressure to abnormal levels during exercise. The systolic blood pressure in the right ventricle is of prognostic import only in that sustained, severe ventricular hypertension imposes a work load that may ultimately cause the heart to fail.

In the absence of an abnormal venoarterial communication, arterial oxyhemoglobin saturation remains normal, and as long as heart failure is absent, dye dilution curves are normal. As end-diastolic pressures in the ventricle rise, particularly with the advent of heart failure, right atrial pressures also increase, in such a circumstance, an incompletely sealed foramen ovale may, as the normal atrial pressure gradient is reversed, become the site of a right-to-left atrial shunt.

Pulmonary stenosis is often associated with atrial or ventricular septal defects. A small patent foramen ovale may be manifested only by slight systemic arterial oxyhemoglobin unsaturation (Selzer et al., 1949), larger atrial defects are more readily detected, in the customary manner, during cardiac catheterization.

When pulmonic stenosis is associated with a large ventricular septal defect, the right ventricular and brachial artery systolic pressures are approximately equal, the recording of a right ventricular systolic blood pressure in excess of systemic is evidence against an overriding aorta or a large ventricular septal defect, since these defects cause both ventricles to empty against a common peripheral resistance and fix blood pressures at approximately equal levels (Soulié et al.).

Fig. 6-52. The anatomic basis for comparing the oxygen contents of right brachial and femoral artery blood in the diagnosis of patent ductus arteriosus with reversal of flow. The left subclavian artery may originate, as in this case, opposite the aortic insertion of the ductus arteriosus, 1 sec after retrograde injection into the left brachial artery (LBA), the contrast material has traversed the left subclavian artery (LSA) and the patent ductus arteriosus (not visualized) to enter the pulmonary artery (PA); with such an anatomic arrangement, in the event of reversal of flow, the left brachial and the femoral arteries receive venous blood from the ductus arteriosus, whereas the right brachial blood is normally saturated (From unpublished data of Blumenthal and Ellis).

One complication of cardiac catheterization in pulmonic stenosis warrants brief mention. In severe stenosis, the entry of the catheter into the pulmonary valve may completely arrest right heart output; this is manifested by the prompt onset of cyanosis and circulatory collapse. Fortunately, this complication is extremely rare. It is generally completely reversible if the catheter is promptly withdrawn.

## TETRALOGY OF FALLOT

Cardiac catheterization in patients with this condition is directed toward the detection of a combination of defects: pulmonic stenosis, high ventricular septal defect, and overriding aorta. The pulmonic stenosis is either infundibular or both infundibular and valvular (Fig. 6-47). The ventricular septal defect is generally large and manifests itself in two ways: (1) by equal systolic blood pressures in the right ventricle and the systemic arteries, and (2) as a channel for access to the aorta from the right ventricle.

Since ventricular pressures are virtually identical, abnormal increments in the oxygen content of blood sampled from the right ven-

monary veins plus atrial septal defect (Swan et al., 1953). Selective angiocardiology may be of some value in these circumstances (Kjellberg).

**Complete Anomalous Drainage.** This anomaly epitomizes the value of a preliminary able clinical assessment for the most fruitful application of the catheterization technique (Keith et al.), this preliminary appraisal defines the vascular and cardiac sites from which blood may be sampled for comparison of oxygen content. The catheter may outline, as it advances, the course of an anomalous vein, its entry into a common pulmonary venous channel, and finally, its insertion. The diagnosis of complete anomalous pulmonary venous return into the more common sites (i.e., superior vena cava, right atrium, or inferior vena cava) is then established by (1) withdrawing highly oxygenated blood from the site of confluence, (2) sampling somewhat less oxygenated blood from a systemic artery, and (3) sampling unsaturated blood from a systemic venous channel en route to the pulmonary venous channels.

These data may be supported by dye-dilution curves, which generally indicate pulmonary recirculation, the return of all right ventricular blood to the right atrium, and a right-to-left atrial shunt (Swan and Wood, 1953). If contrast substance is injected at strategic sites, selective angiocardiology may demonstrate the anomalous veins and the pattern of intracardiac blood flow (Kjellberg et al., 1955).

Pulmonary hypertension may accompany the large increment in pulmonary blood flow.

### EBSTEIN'S DISEASE

Cardiac catheterization plays an important role in establishing this diagnosis (Kilby et al., Kjellberg et al.). The anatomic deformity of the tricuspid valve may complicate or even preclude passage of the cardiac catheter beyond the right atrium. The catheter enters a large right atrium which overlaps the normal

The combination is accounted for by the presence of ventricular muscle in the atrial wall.

Blood pressure in the right atrium may be increased on account of tricuspid insufficiency, altered characteristics of the right atrial wall, and right heart failure. In any event, an increase in right atrial pressure may establish a right-to-left shunt at the atrial level. The catheter tends to slip back from the diminutive right ventricle, which appears to be like an appendage to the huge right atrium. Blood pressures in the right ventricle and pulmonary artery are normal or low; with the advent of right heart failure, end-diastolic pressure in the right ventricle increases. Pulmonary blood flow is low.

Cardiac catheterization in Ebstein's disease may cause various complications. Propensity to runs of atrial and ventricular premature beats suggest a heightened myocardial irritability. Peripheral emboli (Baker et al.) and death (Blacket et al.) have also occurred during the procedure.

### PERSISTENT TRUNCUS ARTERIOSUS

Cardiac catheterization may demonstrate a large ventricular septal defect. The catheter may leave the right ventricle to enter a wide vessel which is continuous with the aortic arch. If the pulmonary branches are sufficiently large, it may be possible to introduce the catheter into one of them. The systolic blood pressure in the ventricles, the arterial trunk, and the pulmonary artery is equal. There is some degree of systemic arterial hypoxemia which is aggravated by exercise.

### TRICUSPID ATRESIA

Cardiac catheterization generally adds little to the clinical diagnosis. The catheter cannot enter the right ventricle by the normal route, it is usually deviated through an interatrial septal defect into the left atrium, it may then enter the common ventricle from which highly oxygenated blood may be sampled. These observations do not distinguish tricuspid stenosis from tricuspid atresia; selective angiocardiology offers most promise in this regard and in the definition of associated anomalies.

### COARCTATION OF THE AORTA

Right heart catheterization has no diagnostic value except to exclude associated anomalies such as a patent ductus arteriosus. Pulmonary

u catheter during attempts to enter the diminutive right ventricle

Simultaneous recording of the intracardiac electrocardiogram and the pressure pulse while the catheter lies in the ventricular portion of the atrium demonstrates an atrial pressure curve and an intraventricular electropotential

Certain extra precautions for protection of patient and physician are, therefore, important. These include adequate dark accommodation before proceeding with the study, the use of protective gloves by the examiner and of aprons by all observers in the room, and adjustment of the fluoroscope shutters so that only the structures under examination are in the field. Additional shielding of the patient's lower abdomen and genitalia is recommended. Maximum settings of the fluoroscope, especially for milliamperage, should be determined and not exceeded. A clock in the fluoroscopy room, which measures the time that the fluoroscope is actually in use, serves as a check on the physician's fluoroscopy practices and a reminder to improve his technique, so that he can obtain the maximum amount of information in the briefest possible fluoroscopy time.

Since most of the patients with congenital heart disease who undergo these radiographic studies are in the pediatric age group, a few words about handling the infant, toddler, and preschool child may be in order. Securing their cooperation is perhaps the most important phase of the study. The time it takes to establish rapport with the young patient is usually time well spent in terms of the results desired: a satisfactory examination. The barium swallow is most apt to be the objectionable part of the examination. No one likes the chalky taste of this mixture, but it can be made quite palatable by the addition of enough sugar and cocoa. Its consistency should be such that it can be swallowed with ease, yet is thick enough to outline the esophagus while the patient is quickly rotated from one position to another. Thus one swallow is sufficient.

Of the age groups involved, the toddler and preschool child are the most likely to present difficulties in cooperation. It is not hard to conceive that the dark fluoroscope room, the strange noises, the big machine, and the curious attire of the examiners in goggles, aprons, and gloves can be unsettling, at least, if not thoroughly frightening. The advent of television has somewhat simplified the preparation of the child for fluoroscopy, since the

fluoroscope screen does resemble that of a television set, and it is customary to view television in a darkened room. Gentle handling by the examiner and the presence of a parent in the room help to get the preschool child satisfactorily through the procedure. Similar technique applies when x-rays are obtained.

Young infants present fewer problems in cooperation than those aged 1 to 4 or 5 years. Best results are obtained when the baby is rested and not hungry and when a pacifier or bottle is available to secure a quiet and relaxed infant for the examination. The baby is less apt to struggle and cry if he is held by the hips for positioning than if his legs, arms, and head are forcibly restrained during the examination.

Children of school age are generally reasonable and cooperative when given an explanation of the purpose of the studies and what is expected of them.

The manner of performance and interpretation of these studies should be systematic, though the technique will vary with the examiner.

The following description is one that the author has found useful in analysis of cardiac chambers and vessels and includes the information obtained by fluoroscopy and roentgenograms together.<sup>2</sup>

The study begins with a survey of the thoracic cage, heart, lungs, and diaphragms. Developmental abnormalities of the vertebrae and ribs sometimes occur together with cardiac defects (Fig. 6-66). Patients with cyanotic congenital cardiac lesions, particularly those associated with diminished pulmonary blood flow, are unusually prone to develop *scoliosis* during adolescence. The lower margins of the ribs should be inspected for evidence of notching or scalloping from vessels of collateral circulation in older children or adults with *coarctation of the aorta* (Fig. 6-66) or cyanotic lesions with severe *pulmonary stenosis*.

The diagnoses were proved at postmortem examination in the patients shown in Figs. 6-56, 6-57, 6-59, 6-61, 6-62, 6-64, 6-65, and 6-70C, and at operation, angiocardiography and/or cardiac catheterization in the patients shown in Figs. 6-55, 6-58, 6-63, 6-66, 6-69, 6-70A, and 6-70B.

subvalvular and valvular types; the idiopathic hypertrophic muscular type, however, differs from the others in significant clinical and hemodynamic respects (Braunwald et al). All are characterized by elevation of the left ventricular systolic pressure and by a systolic gradient across the site of obstruction.

Several approaches to the measurement of the gradient across the aortic obstruction are possible. Retrograde passage of a catheter from the aorta to the left ventricle permits a pressure tracing to be recorded as the catheter is withdrawn from the ventricle past the obstruction into the aorta, defining the severity of the obstruction and its location with respect to the valve [see Fig 6-53(1)]. An additional advantage of this method is that a selective angio-

Fig 6-53(2). Left ventricular pressure obtained by direct puncture compared with central aortic pressure in a patient with aortic stenosis.

cardiogram can be made with the catheter tip in the left ventricle, providing visualization of the obstruction. This is of particular importance in diagnosing the hypertrophic muscular type.

If the catheter cannot be manipulated retrograde across the aortic valve, the aortic pressure recorded through the catheter can be compared with the left ventricular pressure obtained by direct puncture [Fig 6-53(2)] or by the transseptal route (Ross et al) [Fig. 6-53(1)].

Certain extra precautions for protection of patient and physician are, therefore, important. These include adequate dark accommodation before proceeding with the study, the use of protective gloves by the examiner and of aprons by all observers in the room, and adjustment of the fluoroscope shutters so that only the structures under examination are in the field. # Roentgenology in congenital heart disease

MARY ALLEN ENGLE

Of the various radiographic studies that may be performed on patients with heart disease, the two that are the most useful for initial and sequential evaluation are x-rays and fluoroscopy.<sup>1</sup> These are carried out in three projections with the patient in the *frontal* and in both the right and the left *anterior oblique* positions while a radiopaque mixture (usually barium) outlines the adjacent structures at the back of the heart. A lateral x-ray of the chest may be obtained to supplement the other three views but is less informative than the others and should not be used as a substitute for the oblique projections.

X-rays and fluoroscopy enhance each other in yielding important data on chamber and vessel size, as well as activity. X-rays have the advantages of causing less radiation to the patient, of showing greater detail of pulmonary parenchymal and vascular markings, and of permanence of the record for immediate as well as subsequent review. Fluoroscopy has the advantages of motion for judging the degree and sequence of cardiac pulsations and of flexibility of positioning the patient. With the fluoroscope, the heart may be viewed as the patient is rotated, so that each chamber and vessel may be observed to best advantage, thereby providing information that might otherwise be lost if the patient were placed at a set degree of rotation and a film obtained or the fluoroscope turned on. In this manner,

unusual contours that are observed can be analyzed as to position, pulsation, and relation to other structures. Information gleaned from these radiographic studies forms an integral part of the total evaluation of the patient from the points of view of diagnosis, prognosis, and progress of the patient under medical or surgical management.

## GENERAL PRINCIPLES

Technical details of x-ray and fluoroscopy equipment will not be considered here. Suffice it to say that the goal is reproducible clarity of detail of the structures in the thoracic cage and upper abdomen, with minimal radiation of the patient and examiners. For x-rays in the pediatric age group, this necessitates appropriate selection of cones and filters to limit radiation of the infant, toddler, or older child. *Whole body irradiation* of the baby undergoing cardiac evaluation is to be condemned, especially when it is realized that several such studies will be done during the lifetime of the patient born with a congenital cardiovascular anomaly. With advances in medical and surgical therapy for these conditions, the prospects are now good for a great many to reach adulthood and to have children of their own. Protection by appropriate shielding of the lower abdomen and genitalia is desirable. Similar principles apply to fluoroscopy, where irradiation hazard is much greater than with x-rays.

<sup>1</sup> See Part 3, Chap. 8 Editor

The position of the heart in the chest should be noted. Does it lie in the usual position or more to the left or right than is normal? If it lies more in the left chest than it should, has it been displaced there by some abnormality in the right chest, or is the left lung hypoplastic, the left diaphragm elevated? If the heart lies farther to the right than it should, it may be because of displacement or dextro-rotation, or there may be a true mirror-image dextrocardia. A peek at the ECG is of great benefit before the roentgenographic analysis of a dextrocardia. If it is a mirror-image dextrocardia (indicated on the ECG by inversion of the P and T waves in lead I), then the task of interpretation is simplified, because each view as observed is a mirror-image of the normally placed heart. The right and left anterior obliques can be interchanged and the frontal view mirrored mentally on fluoroscopy or simply turned over if an x-ray. Analysis proceeds as for a levocardia. If the heart is not a mirror image but is dextro-rotated, the matter is much more complicated, for the heart may be rotated any amount up to 180°. Landmarks are lost, and one must rely on pulsation to tell which chamber is an atrium, which a ventricle. When dealing with either type of dextrocardia, use of terms "venous" or "pulmonary" and "arterial" or "systemic" atrium and ventricle is recommended instead of "right" or "left," for the latter lead only to helpless confusion in this situation. Sometimes one can use only "anterior" or "posterior" ventricle.

Especially if the heart lies in the right chest, but also for left-sided hearts, it is important to note the position of the diaphragms and the location of the stomach bubble and liver shadow. Occasionally both are on the same side, or there may be complete situs inversus of the abdominal organs (Fig. 6-70B). Diaphragmatic hernia is sometimes associated with congenital cardiac anomalies, particularly ventricular septal defect, and eventration of the diaphragm is occasionally found together with a hypoplastic lung and pulmonary artery as well as anomalies of pulmonary venous return.

#### FRONTAL VIEW

**Heart Size.** An estimate of over-all heart size precedes the more detailed analysis of individual chambers. A simple and reproducible means of estimation is the determination of

the *cardiothoracic ratio*. The greatest transverse cardiac diameter (CD) is the sum of two measurements, from the midline to the outermost right heart border (MR) and from the midline to the most lateral portion of the left heart border (ML). The cardiac diameter is divided by the thoracic diameter (TD), a measurement of the internal thoracic diameter at the level of the dome of the right diaphragm. The average cardiothoracic ratio is 50 per cent, except for infants, where a figure around 55 per cent is more to be expected. In young children, there may be striking changes in this ratio with variations of inspiration and expiration.

Determination of the cardiothoracic ratio is useful for serial evaluation of heart size, especially in the growing child. To find an average or increased cardiothoracic ratio, however, does not necessarily mean that the cardiac chambers are normal in the former or abnormal in the latter situation. For example, there may be marked hypertrophy of the walls of the right or left ventricle, yet, if the chamber is not dilated, the ratio of heart size to thorax may be in normal limits. Familiar examples of this observation are the "concentric hypertrophy" of the left ventricle in aortic stenosis or of the right ventricle in pulmonary stenosis before dilatation of these chambers has occurred. The boot-shaped heart in tetralogy of Fallot, another example, is characteristically small (Fig. 6-69A, B). Hypertrophy of the muscle wall without increase in internal measurements of that cardiac chamber is often better detected by the ECG than by x-rays or fluoroscopy, but certain changes in contour or pulsations of the ventricle may permit radiographic recognition of ventricular hypertrophy. The enlargement of the heart that is easily detected radiographically, therefore, is usually due to dilatation of cardiac chambers alone or in association with hypertrophy of the walls.

Conversely, an increase in cardiothoracic ratio does not always mean cardiac chamber enlargement. Intrapericardial fluid or mass may surround a heart of normal size, and overlying extracardiac masses may simulate cardiac enlargement. A frequent point of confusion in infancy, for example, is thymic enlargement. A well-penetrated chest x-ray may reveal a normal heart shadow within the extracardiac structures, and careful attention to pulsation,

Fig. 6-58. Valvular pulmonic stenosis in a 7-year-old boy. C/T slightly increased. Convex MPA in A.P. and R.A.O.; branches average; periphery clear. RA quite prominent, RV rounded in frontal view; bulges forward in L.A.O. without much displacement posteriorly of LV. LAA without LA enlargement.

with rudimentary right ventricle (Fig 6-55). They may be increased in amplitude with atrial septal defect (Fig 6-61) and diminished in Ebstein's anomaly of the tricuspid valve (Fig 6-59) or in patients who are in atrial fibrillation.

Sometimes the left atrium becomes so enlarged that it forms part of the right heart border beneath the level of the pulmonary artery (Fig 6-67). In such instances, a *double density* can be seen in the region of the atria, and the barium swallow confirms the enlargement of this posterior atrium. When both atria are enlarged, the lower curvature is formed by the right atrium.

Analysis of the left heart border in the frontal view, from the top downward, begins with the aorta. The next convexity in the normal heart is the pulmonary artery and the lowermost projection is the left ventricle.

**Aorta.** The first convexity at the left upper cardiac border is the *aortic knob*, formed by the aorta as it arches to the left and becomes the descending aorta (Fig 6-54). The descending portion of the aorta can be traced down as a linear shadow paralleling and to the left of the vertebral column, seen within the density formed by the pulmonary artery and ventricle.

If the expected convexity of the aortic knob is absent, one should seek the explanation in its being obscured, hypoplastic, or abnormally placed. The normal aortic knob may be obscured by another more laterally positioned vascular or soft-tissue density, such as a left superior vena cava or the thymus. Well-penetrated films will sometimes disclose the aorta within these shadows, and on fluoroscopy, the aortic pulsations can sometimes be detected within the obscuring shadow.

Fig. 6-59. Ebstein's anomaly of tricuspid valve in a 3-year-old boy. C/T moderately increased. Concave MPA in A.P., R.A.O.; hypoplastic branches, clear periphery, RA, RV full in A.P., R.A.O., L.A.O. and under fluoroscope show damped pulsations. L.A.O., marked displacement posteriorly of LV. R.A.O. shows marked posterior bulge of RA, extends behind the esophagus. LAA without LA enlargement.

Fig 6-55. Rudimentary right ventricle with tricuspid atresia, pulmonary stenosis, and atrial septal defect in a 9-month-old boy. Small heart. Concave MPA in AP, and RAO; small RPAs and LPAs, clear lung fields, RA prominent in AP, LAO. In LAO, aorta wide, normally placed; pulmonary window clear

Fig 6-56 Tetralogy of Fallot with infundibular chamber in a 4-year-old girl. Small heart. Concave PA in AP and RAO, small PA branches, clear lung fields. Bulge in RAO. In outflow tract of RV is an infundibular chamber. In LAO, RV bulges forward and the pulmonary window is clear. Ao somewhat dextroposed and enlarged, LAA

Fig 6-57. Infundibular pulmonic stenosis in a 10-year-old girl. C/T slightly increased. Concave MPA, small to average size branches. RV full up to MPA in AP, RAO. RA prominent. LAO shows RV bulges, displacing LV, LPA well seen, Ao, not dextroposed, LAA and no LA enlargement with barium swallow

Fig. 6-58. Valvular pulmonic stenosis in a 7-year-old boy. C/T slightly increased. Convex MPA in A.P. and R.A.O.; branches average; periphery clear. RA quite prominent, RV rounded in frontal view; bulges forward in L.A.O. without much displacement posteriorly of LV. LAA without LA enlargement.

with rudimentary right ventricle (Fig. 6-55). They may be increased in amplitude with atrial septal defect (Fig. 6-61) and diminished in Ebstein's anomaly of the tricuspid valve (Fig. 6-59) or in patients who are in atrial fibrillation.

Sometimes the left atrium becomes so enlarged that it forms part of the right heart border beneath the level of the pulmonary artery (Fig. 6-67). In such instances, a *double density* can be seen in the region of the atria, and the barium swallow confirms the enlargement of this posterior atrium. When both atria are enlarged, the lower curvature is formed by the right atrium.

Analysis of the left heart border in the frontal view, from the top downward, begins with the aorta. The next convexity in the normal heart is the pulmonary artery, and the lowermost projection is the left ventricle.

**Aorta.** The first convexity at the left upper cardiac border is the *aortic knob*, formed by the aorta as it arches to the left and becomes the descending aorta (Fig. 6-54). The descending portion of the aorta can be traced down as a linear shadow paralleling and to the left of the vertebral column, seen within the density formed by the pulmonary artery and ventricle.

If the expected convexity of the aortic knob is absent, one should seek the explanation in its being obscured, hypoplastic, or abnormally placed. The normal aortic knob may be obscured by another more laterally positioned vascular or soft-tissue density, such as a left superior vena cava or the thymus. Well-penetrated films will sometimes disclose the aorta within these shadows, and on fluoroscopy, the aortic pulsations can sometimes be detected within the obscuring shadow.

Concave MPA in A.P., R.A.O.; hypoplastic branches, clear periphery, RA, RV full in A.P., R.A.O., L.A.O. and under fluoroscope show damped pulsations. L.A.O., marked displacement posteriorly of LV. R.A.O. shows marked posterior bulge of RA, extends behind the esophagus. LAA without LA enlargement.

Fig. 6-55. Rudimentary right ventricle with tricuspid atresia, pulmonary stenosis, and atrial septal defect in a 9-month-old boy. Small heart. Concave MPA in AP. and RAO; small RPAs and LPAs, clear lung fields, RA prominent in AP, LAO. In LAO, aorta wide, normally placed, pulmonary window clear.

Fig. 6-56 Tetralogy of Fallot with infundibular chamber in a 4-year-old girl. Small heart. Concave PA in AP and RAO, small PA branches, clear lung fields. Bulge in RAO, in outflow tract of RV is an infundibular chamber. In LAO, RV bulges forward and the pulmonary window is clear. Ao somewhat dextroposed and enlarged, LAA.

Fig. 6-57. Infundibular pulmonic stenosis in a 10-year-old girl. C/T slightly increased. Concave MPA, small to average size branches. RV full up to MPA in AP, RAO. RA prominent. LAO, shows RV bulges, displacing LV, LPA well seen, Ao not dextroposed. LAA and no LA enlargement with barium swallow.

Fig. 6-61. Atrial septal defect in a 6-year-old boy. C/T much increased. Large, convex MPA, large branches with wide pulsations. RA enlarged in A.P.; RV enlarged in A.P., R.A.O., L.A.O.; LV displaced posteriorly in L.A.O. Ao, small in A.P. and L.A.O. and normal in position L.A.O. without LA enlargement.

Fig. 6-62. Ventricular septal defect in a 3-month-old girl. C/T moderately increased. Large, convex MPA in A.P. and R.A.O. with huge branches with increased pulsations. Ao, small in all three views and normally placed in L.A.O. RV full in A.P., R.A.O., L.A.O., LV full in A.P., L.A.O. LAA with some left atrial enlargement in R.A.O.

Fig. 6-63. Patent ductus arteriosus in a 7-year-old boy. C/T slightly increased. PA convex in A.P., R.A.O. Ao wide in all three views and in L.A.O., dilated ascending Ao, with wide-amplitude pulsations under fluoroscope. LV enlargement in A.P., L.A.O. LA enlargement, RV enlargement in L.A.O. and RA enlargement in A.P., somewhat less than enlargement of left heart chambers. LAA.

*Hypoplasia of the aorta* will cause it to cast a smaller-than-normal shadow. This occurs in some situations in which there is a tremendous left-to-right shunt at the ventricular or atrial level, resulting in a very large main pulmonary artery and a small aorta (Figs 6-61 and 6-62). The aorta is also hypoplastic when there is *atresia of the mitral or aortic valves* and the blood supply to the arch of the aorta is provided in retrograde fashion from the pulmonary artery via a patent ductus arteriosus.

*Displacement of the aorta* may occur in several situations

1 The right aortic arch may persist, so that the aorta arches to the right, giving off first the innominate artery on the left side and then in turn, on the right side, the right common carotid and the right subclavian artery. The aorta usually descends on the side to which it arches, so that a right descending aorta is to be expected with a right aortic arch (Fig. 6-69A), but the descending aorta may cross behind the esophagus to the opposite side. This produces an esophageal anterior displacement that is visualized with a barium swallow.

2 The aorta may be normal in size and arch to the left in normal fashion but be pulled out of position by attachment to a fixed structure that retracts it medially. This sometimes occurs in *coarctation of the aorta*, where a short ligamentum arteriosum connects the aorta and the pulmonary artery at the level of the coarctation. Though the aortic knob may not be visible under these circumstances, the enlarged left subclavian artery may at the same time be brought into view as a convex density that goes straight up or somewhat laterally to the apex of the thorax.

3 The aorta may take origin in an abnormal fashion, as in *complete transposition of the great vessels*, where it arises anteriorly and centrally so that it does not cast a shadow at the usual spot for an aortic knob (Fig 6-65). The base of the heart is abnormally narrow in the frontal projection in this condition, but it becomes wider in oblique or lateral views as the vessels are viewed side by side.

Now let us consider a different condition, an aorta that is too prominent. When the ascending aorta is dilated, it forms part of the right heart border just superior to the right branch of the pulmonary artery (Figs 6-63, 6-61, and 6-68). The aorta then sweeps

Fig. 6-60. Differential diagnosis of sites of left-to-right shunts

over to the left to make a large aortic knob as it becomes the descending aorta. The causes for such dilatation are numerous, e.g., when the aorta is the great vessel that receives most of the cardiac output, as in a tetralogy with pulmonary atresia or extreme stenosis, or in a true truncus arteriosus (Fig 6-64). The ascending aorta is dilated when there is an aortic septal defect or large patent ductus arteriosus (Fig. 6-63), both conditions of increased pulmonary arterial, left heart, and aortic blood flow. The aorta is dilated distal in aortic valvular disease, either stenosis (Fig. 6-67) or insufficiency. In the former, the pulsations appear damped and in the latter, bounding. Disease of the aortic wall is another cause of dilatation, as in aortitis, medial necrosis, or aneurysm.

*Pulmonary Artery.* The next area downward along the left heart border is normally a convexity formed by the main pulmonary artery after it leaves the outflow tract of the right ventricle and before it divides into the left and right stems (Fig 6-54). The left stem dips behind the main pulmonary artery and then extends into the left lung as a comma-shaped structure of diminishing size as it branches

Fig. 6-67. Valvular aortic stenosis in an 8-month-old boy. C/T much increased. Pulmonary vascularity average. Dilatation of ascending Ao. In L.A.O. (C). Marked enlargement of LV in A. P. (A), L.A.O. (C). Marked enlargement of LA in R.A.O. (B). LA is border forming in A.P.; note high rounding due to enlargement of LA in contrast to low rounding due to enlarged RA (cf. Fig. 6-61). RV questionably slightly enlarged or displaced forward in L.A.O. (C), R.A.O. (B). LAA.

peripherally. Much of the right pulmonary stem is hidden behind the heart, but when it emerges in the right hilus, it resembles the left branch as it curves downward and vessels fan out from it. Normally, pulsations of small amplitude are visible in the main pulmonary artery and the medial portions of the right and left stems. Deviations from the normal are in the form of diminished or exaggerated convexity and pulsation of these vessels.

Concavity in the region of the main pulmonary artery means that the vessel is atretic, hypoplastic, or misplaced. In the first two situations, the lung fields contain fewer blood vessels than is normal and therefore appear unusually "clear" or radiolucent. The pulmonary artery may be atretic at its origin, and both stems may be absent, in which case there is a concavity in the region of the main pulmonary artery and no hilar "commas." Instead, there is a fine, lacy, stippled appearance in the hilar

regions due to vessels of collateral circulation. Even though there is atresia of the pulmonary artery at its origin, one or both stems may be patent distally, so that a small vessel can be seen in the position of the right or left stem of the pulmonary artery. The heart may be displaced toward the side of an absent pulmonary artery, and the ipsilateral lung may be underdeveloped. It is particularly important to determine the presence or absence of the pulmonary artery on each side if an anastomosis (subclavian-pulmonary or aortopulmonary anastomosis) is contemplated.

More often, when this segment is concave, it is because the main pulmonary artery is hypoplastic. This is usually due to *infundibular pulmonic stenosis*, most often in association with a ventricular septal defect and large aorta, as in the tetralogy of Fallot (Figs 6-56 and 6-69B). Rarely, the infundibular stenosis is an isolated anomaly (Fig 6-57). The small size

Fig. 6-68. Double aortic arch with right descending aorta in a 3-month-old girl. C/T average. Pulmonary blood flow average. In A.P., barium column indented and constricted on both the right and left sides by LAA and by RAA. Barium descends to left of midline, where it is displaced by RDA. R.A.O. and L.A.O.: Esophagus constricted and pushed forward by large vessel the size of an aorta just below region of aortic arch.

*Hypoplasia of the aorta* will cause it to cast a smaller-than-normal shadow. This occurs in some situations in which there is a tremendous left-to-right shunt at the ventricular or atrial level, resulting in a very large main pulmonary artery and a small aorta (Figs 6-61 and 6-62). The aorta is also hypoplastic when there is *atresia of the mitral or aortic valves* and the blood supply to the arch of the aorta is provided in retrograde fashion from the pulmonary artery via a patent ductus arteriosus.

*Displacement of the aorta* may occur in several situations:

1. The *right aortic arch may persist*, so that the aorta arches to the right, giving off first the innominate artery on the left side and then in turn, on the right side, the right common carotid and the right subclavian artery. The aorta usually descends on the side to which it arches, so that a right descending aorta is to be expected with a right aortic arch (Fig 6-69A), but the descending aorta may cross behind the esophagus to the opposite side. This produces an esophageal anterior displacement that is visualized with a barium swallow.

2. The aorta may be normal in size and arch to the left in normal fashion but be pulled out of position by attachment to a fixed structure that retracts it medially. This sometimes occurs in *coarctation of the aorta*, where a short ligamentum arteriosum connects the aorta and the pulmonary artery at the level of the coarctation. Though the aortic knob may not be visible under these circumstances, the enlarged left subclavian artery may at the same time be brought into view as a convex density that goes straight up or somewhat laterally to the apex of the thorax.

3. The aorta may take origin in an abnormal fashion, as in *complete transposition of the great vessels*, where it arises anteriorly and centrally so that it does not cast a shadow at the usual spot for an aortic knob (Fig 6-65). The base of the heart is abnormally narrow in the frontal projection in this condition, but it becomes wider in oblique or lateral views as the vessels are viewed side by side.

Now let us consider a different condition: an aorta that is too prominent. When the ascending aorta is dilated, it forms part of the right heart border just superior to the right branch of the pulmonary artery (Figs 6-63, 6-64, and 6-66). The aorta then sweeps

Fig. 6-60. Differential diagnosis of sites of left-to-right shunts.

over to the left to make a large aortic knob as it becomes the descending aorta. The causes for such dilatation are numerous, e.g., when the aorta is the great vessel that receives most of the cardiac output, as in a tetralogy with pulmonary atresia or extreme stenosis, or in a true truncus arteriosus (Fig 6-64). The ascending aorta is dilated when there is an aortic septal defect or large patent ductus arteriosus (Fig 6-63), both conditions of increased pulmonary arterial, left heart, and aortic blood flow. The aorta is dilated distal in aortic valvular disease, either stenosis (Fig. 6-67) or insufficiency. In the former, the pulsations appear damped and in the latter, bounding. Disease of the aortic wall is another cause of dilatation, as in aortitis, medial necrosis, or aneurysm.

**Pulmonary Artery.** The next area downward along the left heart border is normally a convexity formed by the *main pulmonary artery* after it leaves the outflow tract of the right ventricle and before it divides into the *left and right stems* (Fig 6-54). The left stem dips behind the main pulmonary artery and then extends into the left lung as a comma-shaped structure of diminishing size as it passes

the lung fields should be inspected by x-ray and fluoroscopy for evidences of other vascular anomalies. A pulsating density, of a size out of proportion to the normal vessels in that segment of lung, suggests an *arteriovenous fistula*. A vascular shadow that does not follow the normal fanning-out pattern of the branching arterial tree suggests an *anomalously draining pulmonary vein*. Multiple thin transverse lines at the lung bases are found in some patients with pulmonary venous congestion and are thought to represent *prominent lymphatic channels*. A peculiar, evenly stippled appearance to the lung fields is observed in some patients with *infradiaphragmatic total anomalous pulmonary venous drainage*. Presumably this pattern is due to *pulmonary venous obstruction*. A similar picture may be observed in pulmonary hemosiderosis.

Though the arterial supply and venous drainage of the lungs are usually bilaterally symmetrical, the two sides may be quite different. For example, one side may be devoid of a pulmonary artery and the other lung normally filled or flooded. Vessels of collateral circulation to the lungs may be better devel-

oped on one side than the other. Therefore, the two lung fields should be inspected individually and compared with each other, as well as with the mental image of the normal pulmonary vascular bed.

**Left Ventricle.** In the normal person, the next and lowermost bulge on the left heart border represents the left ventricle. But, under certain circumstances of left atrial or right ventricular enlargement, an additional convexity is interposed: the *left auricular appendage* or the *outflow tract of the right ventricle*. It can be decided which of these chambers is responsible for the enlargement by noting the timing and character of pulsations to determine whether they are atrial or ventricular and by seeking other evidences of enlargement of these chambers: deviation of the barium-filled esophagus by an enlarged left atrium and fullness of the outflow tract of the right ventricle in the RAO projection.

The apex of the heart is usually formed by the left ventricle. If the apex extends too far laterally, there may be enlargement of one or both of the ventricles. Oblique projections are often more helpful in telling which ventricle,

Fig. 6-69. A. Right aortic arch and right descending aorta in a 19-year-old boy. Aortic knob absent on left but visible on right within shadow of SVC which it displaces laterally. Barium column curves to left around the RAA and descends to left of midline, displaced there by RDA. Small heart with RV enlargement, slightly convex MPA, hypoplastic right and left branches and clear lung fields. Patient has tetralogy of Fallot with valvular pulmonic stenosis. B. Retroesophageal right subclavian artery in a 9-year-old girl. Barium swallow reveals oblique filling defect from below on left side upward to right side. Barium curves to right around the LAA and descends in midline adjacent to LDA. Aortic knob and descending aorta well seen on left side. Small boot-shaped heart with RV enlargement, concave MPA segment, and clear lung fields in patient with tetralogy of Fallot. C. Retroesophageal vessel of collateral circulation in the lungs in a 3-month-old boy. Note sharp incurving of esophagus about level of pulmonary arteries. This is due to a vessel of collateral circulation arising from the descending aorta and coursing behind the esophagus to anastomose with pulmonary arteries in the lung fields. A continuous murmur over the lung fields posteriorly was produced during life by this vessel. Infant with tetralogy of Fallot and pulmonary atresia (pseudotruncus arteriosus).

Fig. 6-64. Common trunkus arteriosus in a 6-month-old girl. C/T markedly increased. MPA region concave in AP, RAO; yet large PA branches with increased pulsations. "Aorta" wide in all three views. LV greatly enlarged in AP, and LAO. RV also enlarged, but less than LV, in LAO, RAO. LA forms a double density in AP. Esophagram (not shown in these pictures) confirmed LA enlargement.

Fig. 6-65. Complete transposition of the great vessels in a 1-month-old boy. C/T much increased. MPA region concave in AP and RAO, yet large PA branches and increased pulmonary vascular markings throughout. Base of heart narrow in AP, and twice as wide in LAO, and LAO. LV enlargement (AP, and LAO) and RV enlargement (AP, LAO, and LAO). Atria less enlarged. Barium swallow not reproduced well, slight LA enlargement.

Fig. 6-66. Coarctation of aorta in an 18-year-old boy. C/T average. Pulmonary blood flow average. MPA obscured within shadow of dilated descending Ao. Convexity of aortic knob above that of poststenotic segment of descending Ao. Dilated ascending Ao in AP. Barium swallow in RAO, and left lateral shows anterior displacement of esophagus by poststenotic dilatation of descending Ao. LA enlargement. LAA. Scalloping of undersurface of ribs bilaterally. Congenital anomaly of rib cage on left.

the lung fields should be inspected by x-ray and fluoroscopy for evidences of other vascular anomalies. A pulsating density, of a size out of proportion to the normal vessels in that segment of lung, suggests an *arteriovenous fistula*. A vascular shadow that does not follow the normal fanning-out pattern of the branching arterial tree suggests an *anomalously draining pulmonary vein*. Multiple thin transverse lines at the lung bases are found in some patients with pulmonary venous congestion and are thought to represent *prominent lymphatic channels*. A peculiar, evenly stippled appearance to the lung fields is observed in some patients with *infradiaphragmatic total anomalous pulmonary venous drainage*. Presumably this pattern is due to *pulmonary venous obstruction*. A similar picture may be observed in *pulmonary hemosiderosis*.

Though the arterial supply and venous drainage of the lungs are usually bilaterally symmetrical, the two sides may be quite different. For example, one side may be devoid of a pulmonary artery and the other lung normally filled or flooded. Vessels of collateral circulation to the lungs may be better devel-

oped on one side than the other. Therefore, the two lung fields should be inspected individually and compared with each other, as well as with the mental image of the normal pulmonary vascular bed.

**Left Ventricle.** In the normal person, the next and lowermost bulge on the left heart border represents the left ventricle. But, under certain circumstances of left atrial or right ventricular enlargement, an additional convexity is interposed: the *left auricular appendage* or the *outflow tract of the right ventricle*. It can be decided which of these chambers is responsible for the enlargement by noting the timing and character of pulsations to determine whether they are atrial or ventricular and by seeking other evidences of enlargement of these chambers: deviation of the barium-filled esophagus by an enlarged left atrium and fullness of the outflow tract of the right ventricle in the RAO projection.

The apex of the heart is usually formed by the left ventricle. If the apex extends too far laterally, there may be enlargement of one or both of the ventricles. Oblique projections are often more helpful in telling which ventricle,

Fig. 6-69. A. Right aortic arch and right descending aorta in a 19-year-old boy. Aortic knob absent on left but visible on right within shadow of SVC which it displaces laterally. Barium column curves to left around the RAA and descends to left of midline, displaced there by RDA. Small heart with RV enlargement, slightly convex MPA, hypoplastic right and left branches and clear lung fields. Patient has tetralogy of Fallot with valvular pulmonic stenosis. B. Retroesophageal right subclavian artery in a 9-year-old girl. Barium swallow reveals oblique filling defect from below on left side upward to right side. Barium curves to right around the LAA and descends in midline adjacent to LDA. Aortic knob and descending aorta well seen on left side. Small boot-shaped heart with RV enlargement, concave MPA segment, and clear lung fields in patient with tetralogy of Fallot. C. Retroesophageal vessel of collateral circulation to the lungs in a 3-month-old boy. Note sharp incurving of esophagus about level of pulmonary arteries. This is due to vessel of collateral circulation arising from the descending aorta and coursing behind the esophagus to anastomose with pulmonary arteries in the lung fields. A continuous murmur over the lung fields posteriorly was produced during life by this vessel. Infant with tetralogy of Fallot and pulmonary atresia (pseudotruncus arteriosus).

of the pulmonary artery is evident in the stems as well. Under the fluoroscope, pulsations are diminished to absent in these vessels.

*Displacement of the pulmonary artery* as a cause of concavity in that region comes about either through rotation of the heart or through malposition of the vessel itself. Examples of rotational changes are the varying degrees of congenital dextrorotation of the heart, as well as great enlargement of the left ventricle, so that the pulmonary artery is rotated out of view. In either event, where rotation is a factor, the convex pulmonary artery can usually be located when the patient is turned into the oblique projections.

*Actual malplacement of the pulmonary artery* with resultant concavity of the pulmonary artery segment occurs chiefly in the following two conditions: (1) When there is complete transposition of the great vessels (Fig. 6-65), the pulmonary artery arises from the left ventricle as the posterior great vessel, and in "corrected" transposition complexes, the pulmonary artery arises posteriorly and medially. (2) When there is a common truncus arteriosus (Fig. 6-64), the pulmonary stems arise from the common trunk, usually at a distance from the outflow tract of the ventricle. In transposition complexes, as well as in true truncus arteriosus, the pulmonary blood flow is unobstructed and is greater than normal, so that the lung fields appear "plethoric" and under the fluoroscope the pulmonary artery branches may exhibit increased pulsations. In an infant with congenital heart disease the combination of concave pulmonary artery segment and flooded lung fields should suggest a transposition of the great vessels or truncus arteriosus. In the former, the base of the heart appears narrow in the frontal view, where the two vessels lie one in front of the other, but the base broadens in the oblique projections as the vessels are seen side by side. In the latter, the base of the heart is equally wide in all views when there is a single large truncus.

Unusual convexity of the pulmonary artery is due to dilatation of that vessel, which can occur for several reasons: (1) Dilatation is distal to valvular pulmonary stenosis (Fig. 6-58) or proximal to peripheral pulmonary artery stenoses or pulmonary venous obstruction. (2) The dilatation may be due to increased volume of pulmonary blood flow associated with

a large arteriovenous shunt at the atrial, ventricular, or aortopulmonary levels (Figs. 6-60 to 6-63). (3) There is a rare situation, designated *idiopathic dilatation of the pulmonary artery*, where no functional abnormalities can be detected to account for the large size of the pulmonary artery. The dilatation in any of these situations may assume aneurysmal proportions.

*Pulmonary Vascular Bed.* The nature of the pulmonary vasculature beyond the dilated vessel serves to differentiate the causes of the dilatation. When there is *valvular pulmonary stenosis* (Fig. 6-58), the right and left stems decrease quickly in size and the peripheral pulmonary vasculature is clearer than usual, especially if there is a right-to-left shunt, so that the pulmonary circulation is actually depleted. Though pulsations may be seen in the main pulmonary artery, where the jet of blood coming through the stenosed valve strikes the wall and swirls about, the pulsations in the stems are reduced or absent.

If the obstruction is distal to the valve and is in the peripheral pulmonary arteries or arterioles, the pulmonary stems or branches are enlarged out to the region of obstruction, around the middle third of the lung field (going from hilus to periphery), then stop abruptly and the peripheral lung fields are excessively clear. If the obstruction is distal to the pulmonary arterioles, the pulmonary arteries are enlarged throughout and taper gradually. In addition, there may be a hazy appearance to the lung fields due to pulmonary venous distention. Pulsations in the main pulmonary artery and its branches may be more vigorous than normal but are less prominent than those seen in enlarged pulmonary arteries when there is a left-to-right shunt.

In lesions where the volume of pulmonary blood flow greatly exceeds the systemic flow, the main pulmonary artery and branches are engorged and overactive. In the hilar areas, round densities representing pulmonary artery branches seen end on are found (Figs. 6-61 to 6-63 and 6-70C). Pulsations in the pulmonary arteries are exaggerated, especially if the malformation is an atrial or ventricular septal defect. The *hilar dance* in patients with patency of the ductus arteriosus is usually less marked than with septal defects.

While viewing the pulmonary arterial tree,

developed right ventricle, the entire anterior aspect of the heart in this view is formed by the right atrium (Fig. 6-55), which can be seen to pulsate before the posteriorly placed left ventricle. The right atrium may pulsate more vigorously than normal in patients with tricuspid atresia, but in Ebstein's anomaly of the tricuspid valve (Fig. 6-59) (another example where the right atrium can form the anterior cardiac border in the LAO projection), the pulsations are quite damped. When the tricuspid leaflets are plastered down against the right ventricular wall, so that their free margins divide that chamber into a distal portion that functions as a right ventricle and a proximal chamber that is atrialized, the proximal portion becomes dilated and exceedingly thin-walled. Its pulsations may be barely perceptible and are in contrast to the normal pulsations of the left ventricle behind.

Right ventricular pulsations are often increased in vigor or amplitude in those conditions causing enlargement of that ventricle. When the right ventricle enlarges, it bulges not only forward but backward as well, displacing the left ventricle posteriorly (Figs. 6-57, 6-59, and 6-61). It may then be very difficult to decide about the size of the left ventricle: whether it is also enlarged or is merely pushed back. If the patient can take a deep enough breath so that the interventricular groove on the bottom of the heart can be visualized, this question can be answered. The groove marks the separation between anterior and posterior ventricle. It should be at the mid-point between anterior and posterior heart border if the ventricles are of equal size, but is displaced posteriorly by enlargement of the right ventricle. Unfortunately, in patients with much ventricular enlargement, the ventricles cover so much of the diaphragmatic surface that the groove cannot be seen, either with a deep breath or with the stomach filled with carbonated beverages for better contrast. Radiographically, to determine left ventricular enlargement in the presence of much right ventricular enlargement, one must sometimes rely on collateral evidence of left-sided involvement. For example, the presence of left atrial enlargement or aortic abnormality would be in favor of left ventricular enlargement.

The posterior aspect of the heart shadow

in the LAO projection is formed by the aortic arch above, the pulmonary stems just below that, then the left atrium, and the bulk of the shadow by the left ventricle.

The transverse arch and descending aorta in this view have been alluded to. *Coarctation of the aorta* with poststenotic dilatation (Fig. 6-66), *aneurysms* in this region, and the absence of the descending aorta on the left because it descends on the right are the chief abnormalities to be reckoned with.

Deviations in the pulmonary stems and branches, which normally fill the aortic window, are next in line for analysis. Diminutive size of the pulmonary stems produces an unusually clear window, especially if the aorta is at the same time dextroposed, as in *tetralogy of Fallot* (Fig. 6-56). Large and abnormally pulsating pulmonary arteries are also well seen in this view (Fig. 6-62).

The left atrium lies just beneath the bifurcation of the bronchi and atop the left ventricle. Unless it enlarges considerably, so that it displaces the left main bronchus upward, the left atrium is not well seen in this view. Fortunately, however, the esophagus hugs the posterior wall of the left atrium and can be filled with contrast medium, so that changes in size of that chamber can more readily be perceived. This will be discussed later under the heading Esophagram.

The major portion of the posterior cardiac border in the LAO projection is formed by the left ventricle. Its relationship to the vertebral column forms a convenient way of estimating left ventricular or cardiac size. In the normal person with quiet respirations, the posterior border of the heart (the left ventricle) clears the anterior border of the vertebrae at 50° of rotation. Increase in this angle of clearance is due to left ventricular enlargement or displacement or to extracardiac fluid or mass.

## RIGHT ANTERIOR OBLIQUE POSITION

The patient is turned into the RAO position, so that his right shoulder is next to the fluoroscopic screen and the heart no longer overlaps the spine. The right ventricle, its outflow tract, and the main pulmonary artery are in silhouette anteriorly, with the aorta at the top. The left atrium forms the posterior heart border.

but in the frontal view there are certain clues that point to one or the other. If the apex extends outward and downward toward the diaphragm, the left ventricle is suspect (Figs. 6-63 and 6-64). But if the apex is tipped outward and upward, so that it points away from the diaphragm (Figs. 6-56 and 6-59B) or if the rounding of the apex begins high beneath the pulmonary artery (Figs. 6-57 to 6-59 and 6-61), this is probably due to enlargement of the right ventricle, which has displaced the left ventricle outward and upward or which has enlarged to such an extent that it forms the apex of the heart. Enlargement of both ventricles produces a combination of these findings: the ventricular shadow bulges downward, outward, and upward, but marked enlargement of either ventricle alone can duplicate these changes (Fig. 6-61). At this stage, rotation of the patient into the LAO projection helps. Here, the right ventricle comes forward and the left ventricle forms the posterior heart border, and each can be seen to better advantage.

#### LEFT ANTERIOR OBLIQUE POSITION

Nomenclature has been standardized for the oblique views, so that the cardiac chambers are

viewed in the same projection, regardless of whether the fluoroscope screen is next to the patient's left side (as it is in the LAO view) or the x-ray cassette is against his right side.

In this projection, the uppermost shadow is formed anteriorly by the aorta as it ascends. It arcs posteriorly and becomes more difficult to visualize as it descends because it is superimposed on the vertebral column. This projection is an excellent one for determining dilatation of the ascending aorta (Figs. 6-63 and 6-67), transposition (Fig. 6-65), or marked dextroposition of the aorta (Fig. 6-56). When the aorta arises abnormally far forward, it must make a wider sweep in the transverse portion before it descends. Thus there is a wide aortic window, that area between the posterior aspect of the ascending aorta and the anterior portion of the descending aorta.

The right atrium (above) and the right ventricle (below) form the anterior aspect of the heart in the LAO projection. Enlargement of either or both of these chambers will cause a forward bulge of the cardiac shadow (Figs. 6-55 to 6-59 and 6-61). Fluoroscopic timing of pulsations will tell whether atrium or ventricle is responsible for the enlargement.

In instances of tricuspid atresia with under-

Fig. 6-70 A Situs inversus with dextrocardia in an 8-year-old boy. Small heart with apex on right, stomach bubble on right. Note bilateral SVC, concave MPA segment on right, average-sized PA branches, and convexity in region of outflow tract of ventricle. The latter is a rudimentary outlet chamber in this patient who has a single ventricle and slight pulmonic stenosis. B Situs inversus with levocardia in a 5-year-old girl. C/T not increased. Apex on left. Stomach bubble on right. Liver on left. Straight shadows on right and left at base of heart represent bilateral SVC. Concave MPA. Slightly decreased pulmonary vascularity. C. Total anomalous pulmonary venous return to left superior vena cava in a 42-year-old woman. C/T increased. Pulmonary blood flow much increased. RA enlargement and RV enlargement. Great vascular collar (for left innominate vein), which is greatly dilated, as is superior vena cava on right, which receives this admixed blood and leads it into RA, RV, and PAs. Small atrial septal defect was only entry of blood into left side of heart and systemic circulation.

When coarctation of the aorta occurs at the usual place below the left subclavian artery, and there is poststenotic dilatation of the descending aorta, this dilated area acts as a retroesophageal vessel and bows the barium column forward in the LAO projection (Fig. 6-66). If intercostal arteries become much enlarged in patients with coarctation, these too are small retroesophageal vessels which can be identified on barium swallow.

Sometimes, in patients with great enlargement of the pulmonary artery and its main stems, there can be seen in the LAO projection a forward displacement of the esophagus at the level of the pulmonary artery branch.

Equal attention is paid to the esophagus, where it is in contact with the left atrium. In acquired heart disease, this is the chief point of interest in the esophagram because of the information to be obtained about the size of the left atrium. One should not rely on a single view to determine the presence or absence of left atrial enlargement, because different degrees of enlargement may affect the esophagus in various ways, so that even gross enlargement may be missed if the barium swallow is done in only one view. One may gain a false impression of left atrial enlargement if the esophagus is not completely filled or if the diaphragms are elevated. In this respect, fluoroscopy has an advantage over films in eliminating these artifacts.

The single most useful view for detecting the various degrees of left atrial enlargement is the RAO projection, where the esophagus is deviated posteriorly in a greater or lesser curvature, depending on the degree of enlargement (Figs 6-62, 6-63, and 6-67).

At the same time that the esophagus bows posteriorly in the RAO projection, it curves to the right and then swings back to the midline in the frontal view.

If the esophagus has been displaced, as described in the above two views, it usually falls undisturbed in the LAO projection.

Occasionally, however, the esophagus swings to the left of the midline in the frontal projection, curves posteriorly in the LAO projection, and falls straight in the RAO view. This is particularly true if the left atrium is markedly enlarged.

In the lateral view, the esophagus swings posteriorly if it is displaced by a large left

atrium, but may not be deviated at all in slight degrees of enlargement, and with some enlargement the barium column may be displaced more in one or the other of the obliques than in the lateral view.

Therefore, to evaluate the size of the left atrium by its effect on the adjacent esophagus, it is important to visualize the esophagus in multiple projections.

## INTERPRETATION OF RESULTS

When the various pieces of information have been gleaned from a careful perusal of the x-rays and fluoroscopy of the heart and lungs in the frontal and both oblique projections, they must be assembled for a working diagnosis of the patient's heart condition. The final clinical impression should be a synthesis of all pertinent information—the history, physical findings, ECG, and indicated special procedures as well as radiologic studies. No single piece of information should be assigned diagnostic significance out of context with other available data. Each part of the diagnostic work-up has much to offer, and when all parts are considered together, a sound diagnosis can usually be reached.

It is important that some clinical information be available at the time of analysis of radiographic studies because a different interpretation may be in order if it is known that the patient is cyanotic, for example, rather than of normal color. And the findings will be interpreted with greater caution if it is known that the patient is in heart failure than if it is assumed that the abnormalities observed are the usual condition for that patient. If the patient has an acute febrile illness suggesting pneumonia, interpretation of the markings in the lung fields might be more in favor of bronchopneumonia than of increased pulmonary blood flow or congestive heart failure, conditions that would be suggested in a patient without a history of respiratory infection. Incidentally, the precise recognition of superimposed bronchopneumonia or left-sided heart failure in an infant or child with greatly increased pulmonary blood flow is fraught with difficulty.

With these reservations then, let us consider how a radiologic diagnosis is reached. The most difficult conditions to diagnose are in those patients with congenital heart disease

The normal right ventricle curves gently upward, then gives off a normally convex main pulmonary artery (Fig. 6-54). Right ventricular enlargement exaggerates this curve (Figs. 6-56 to 6-59 and 6-61). The ventricle may extend to the chest wall and even be flattened against it for several centimeters. It should be noted that marked left ventricular enlargement can be solely responsible for an extension of the cardiac silhouette forward and downward in this view, thus suggesting associated right ventricular enlargement. This problem in differential diagnosis of ventricular enlargement may be resolved by finding associated signs of right-sided cardiac enlargement, e.g., evidence of enlargement of the pulmonary artery or of the right atrium, which would favor the presence of right ventricular enlargement. The ECG may also help.

If there is *infundibular pulmonary stenosis*, the outflow tract of the right ventricle has a scooped-out concave appearance in this and the frontal view (Fig. 6-57). The RAO position is excellent for detecting an infundibular chamber distal to infundibular narrowing. The chamber can be identified as a separate bulge in the outflow portion of the ventricle proximal to the region of the main pulmonary artery (Fig. 6-58). A rudimentary outlet chamber in a patient with a single ventricle has a similar appearance (Fig. 6-70A).

The main pulmonary artery, as it springs from the right ventricle, is seen to best advantage in the RAO projection. Unusual concavity or convexity has the same significance as described in the frontal projection. Occasionally, the main pulmonary artery may be more centrally placed than is usual, so that the pulmonary artery segment in the frontal view is concave. Careful search as the patient is rotated into the RAO projection may reveal it as a normally convex structure.

The left atrium forms the posterior cardiac border. Behind it lies the esophagus. This is the most sensitive position for detecting slight, as well as gross, degrees of left atrial enlargement by the posterior swing of the barium-filled esophagus around the left atrium.

Occasionally, the right atrium may be so enlarged that it projects far backward, overlapping the left atrium and forming the posterior margin of the heart (Fig. 6-59). Barium swallow serves to differentiate right from left

atrial enlargement under these circumstances: if there is no displacement of the barium-filled esophagus in this or other views, it is the right atrium, not the left, that is responsible for the posterior curve.

## LATERAL VIEW

This is the least valuable of the four positions for discrete analysis of cardiac chambers and vessels. One can sometimes gain the impression that the heart is enlarged more anteriorly than posteriorly and that the retrosternal space has been encroached upon more than is normal, but other projections are needed for confirmation. Marked degrees of left atrial enlargement may produce more deviation of the barium-filled esophagus in this view than in the others.

## ESOPHAGRAM

When a patient is being fluoroscoped, a swallow of thick contrast material (usually barium) to outline the esophagus, as the patient is rotated through the three views, completes the study. For chest x-rays also, the esophagus should be filled with barium in all three views. This necessitates three swallows of the chalky mixture. Therefore, especially for children, the few minutes required to flavor the mixture for palatability and to make it thick enough so that it does not disappear before the picture is taken represent time well spent.

In the frontal view, the esophagus curves to the right at the level of the aorta which arches to the left and then descends straight down the midline behind the left atrium and to the right of the descending aorta to pass through the diaphragm and into the stomach on the left (Fig. 6-54).

When dealing with patients with congenital cardiac anomalies, it is well to maintain an interest in the course of the barium until it is in the stomach, for in this way one can identify some developmental anomalies of the gastrointestinal tract as well: complete or partial situs inversus of the abdominal organs in patients with *levocardia* (Fig. 6-70B) or *dextrocardia* (Fig. 6-70A). Often these anomalies are suspected before the barium swallow, but it usually comes as quite a surprise to find, in a patient where the liver has been palpated or percussed in the right upper quadrant, that

When coarctation of the aorta occurs at the usual place below the left subclavian artery, and there is poststenotic dilatation of the descending aorta, this dilated area acts as a retroesophageal vessel and bows the barium column forward in the LAO projection (Fig. 6-63). If intercostal arteries become much enlarged in patients with coarctation, these too are small retroesophageal vessels which can be identified on barium swallow.

Sometimes, in patients with great enlargement of the pulmonary artery and its main stems, there can be seen in the LAO projection a forward displacement of the esophagus at the level of the pulmonary artery branch.

Equal attention is paid to the esophagus, where it is in contact with the left atrium. In acquired heart disease, this is the chief point of interest in the esophagram because of the information to be obtained about the size of the left atrium. One should not rely on a single view to determine the presence or absence of left atrial enlargement, because different degrees of enlargement may affect the esophagus in various ways, so that even gross enlargement may be missed if the barium swallow is done in only one view. One may gain a false impression of left atrial enlargement if the esophagus is not completely filled or if the diaphragms are elevated. In this respect, fluoroscopy has an advantage over films in eliminating these artefacts.

The single most useful view for detecting the various degrees of left atrial enlargement is the RAO projection, where the esophagus is displaced posteriorly in a greater or lesser curvature, depending on the degree of enlargement (Figs. 6-62, 6-63, and 6-67).

At the same time that the esophagus bows posteriorly in the RAO projection, it curves to the right and then swings back to the midline in the frontal view.

If the esophagus has been displaced, as described in the above two views, it usually falls undisturbed in the LAO projection.

Occasionally, however, the esophagus swings to the left of the midline in the frontal projection, curves posteriorly in the LAO projection, and falls straight in the RAO view. This is particularly true if the left atrium is markedly enlarged.

In the lateral view, the esophagus swings posteriorly if it is displaced by a large left

atrium, but may not be deviated at all in slight degrees of enlargement, and with some enlargement the barium column may be displaced more in one or the other of the obliques than in the lateral view.

Therefore, to evaluate the size of the left atrium by its effect on the adjacent esophagus, it is important to visualize the esophagus in multiple projections.

## INTERPRETATION OF RESULTS

When the various pieces of information have been gleaned from a careful perusal of the x-rays and fluoroscopy of the heart and lungs in the frontal and both oblique projections, they must be assembled for a working diagnosis of the patient's heart condition. The final clinical impression should be a synthesis of all pertinent information—the history, physical findings, ECG, and indicated special procedures as well as radiologic studies. No single piece of information should be assigned diagnostic significance out of context with other available data. Each part of the diagnostic work-up has much to offer, and when all parts are considered together, a sound diagnosis can usually be reached.

It is important that some clinical information be available at the time of analysis of radiographic studies because a different interpretation may be in order if it is known that the patient is cyanotic, for example, rather than of normal color. And the findings will be interpreted with greater caution if it is known that the patient is in heart failure than if it is assumed that the abnormalities observed are the usual condition for that patient. If the patient has an acute febrile illness suggesting pneumonia, interpretation of the markings in the lung fields might be more in favor of bronchopneumonia than of increased pulmonary blood flow or congestive heart failure, conditions that would be suggested in a patient without a history of respiratory infection. Incidentally, the precise recognition of superimposed bronchopneumonia or left-sided heart failure in an infant or child with greatly increased pulmonary blood flow is fraught with difficulty.

With these reservations then, let us consider how a radiologic diagnosis is reached. The most difficult conditions to diagnose are in those patients with congenital heart disease

the barium curves to the right below the diaphragm to enter a stomach that is also in the right upper quadrant.

In the LAO projection, the barium mixture falls straight down, without indentation by structures in front or behind (Fig. 6-51).

In the RAO view, the barium column curves posteriorly about the left aortic arch and then hugs the back of the heart as it descends in a straight line, without indentation, toward the stomach (Fig. 6-51). In infancy, the aorta as it arches may impinge very little on the esophagus. One then identifies the left aortic arch because there is evidence of a left descending aorta and no retroesophageal vessels.

The structures which cause any departure from the above course of the esophagus are the aorta, or some of its branches, and the left atrium. Neither the right atrium nor right or left ventricle is in contact with the esophagus and, therefore, cannot alter the esophagram.

One of the common aortic anomalies is a *right aortic arch and descending aorta*. This can occur as an isolated abnormality or in association with other cardiac anomalies. It is found in about 25 per cent of patients with a tetralogy of Fallot. Persistence of the right aortic arch gives a mirror image of the normal course of the aorta and a mirror image of the normal esophagram. In frontal view, the barium curves to the left at the level of the right aortic arch, and it descends to the left of the midline, where it is displaced by the *right descending aorta* (Fig. 6-69A). In the LAO projection, the barium curves posteriorly at the level of the arch, and in the RAO view, it falls freely without indentation. Rarely does the aorta pass behind the esophagus before arching to the right.

Sometimes the aorta arches to one side, then crosses over high in the thorax and descends on the opposite side. If it does so, the side of the arch is identified by the direction it displaces the esophagus in the frontal and oblique projections, as described above. Then the esophagus kinks abruptly or obliquely in the frontal view as the aorta crosses behind it, and in the oblique projections, the esophagus curves forward around the retroesophageal aorta. The side on which the aorta descends is identified in the frontal view by whether the barium descends in the midline (left descending aorta) or to the left

of the midline. One can also visualize the descending aorta if the patient is turned into the oblique projection corresponding to the side on which the aorta descends, e.g., RAO for right-sided descending aorta.

Here is an illustration of such an analysis: if the barium curves to the right in the frontal and RAO views, there is a left aortic arch. A large forward bowing of the esophagus just below the level of the aortic arch indicates a retroesophageal course of the aorta, and the descent of the barium column in frontal view to the left of the midline confirms the fact that the aorta has crossed over to descend on the right side (Fig. 6-68).

A similar analysis holds for patients with a *vascular ring* and a *double aortic arch* (Fig. 6-68). Each component is identified by the manner in which it affects the esophagus. However, if one part of the ring is hypoplastic or a ligament, then the presence of only the well-developed arch and a retroesophageal vessel will be manifest.

Other aortic arch anomalies recognizable by changes in the esophagram produce a forward displacement of the esophagus in one or both oblique views because of their retroesophageal location. These include *aberrant right subclavian artery* (Fig. 6-69B), *anomalous vessels of collateral circulation from aorta to lungs* (Fig. 6-69C), and *coarctation of the aorta* (Fig. 6-66).

Aberrant right subclavian artery comes off below the left subclavian artery as the last of the brachiocephalic vessels, and it crosses behind the esophagus and obliquely upward to enter the right arm. Thus in the oblique projections the esophagus is pushed forward, and in the frontal view there is an *oblique filling defect*, low on the left and high on the right side (Fig. 6-69B). Aberrant subclavian artery has been associated with *dysphagia lusoria*, but in the pediatric age group symptoms are rare.

Anomalous vessels from the aorta to the lungs alter the barium swallow when they come off the descending aorta and pass behind the esophagus to anastomose with the pulmonary arteries. These collaterals may be single or multiple, and if of sufficient size, they indent the esophagus on its posterior aspect and can be identified in oblique or lateral views (Fig. 6-69C).

amount of blood. The systemic venous return plus the large volume of arterial blood travel through the right atrium, ventricle, and pulmonary artery, all of which are dilated. The left ventricle and aorta, by contrast, receive a smaller amount of blood and are not enlarged. Compared to the pulmonary artery, the aorta is the smaller vessel and may be normal in size or hypoplastic. Unless there is obstruction to outflow from the right ventricle (pulmonary stenosis or increased pulmonary vascular resistance), there is not much hypertrophy of the wall of the right ventricle.

If the shunt occurs distal to the AV valves, the augmented pulmonary blood flow is returned to the left atrium and the left ventricle before partitioning, so left ventricular enlargement (dilatation and hypertrophy) appears. If the shunt is at the ventricular level, then part of this blood enters the right ventricle and pulmonary artery, which are dilated. The remainder enters the aorta in normal or subnormal amount, so that the aorta is actually or relatively small in comparison with the pulmonary artery.

If the shunt is at the aortopulmonary level, the large amount of blood returning from the

lungs passes through the left atrium, left ventricle, and crosses the aortic valve into the aorta before it divides—at the region of the descending aorta (if there is a patent ductus arteriosus) or in the ascending aorta (if there is an aortoseptal defect). Therefore, the aorta is dilated in aortopulmonary shunts, whereas it is not when the shunt is at the atrial or ventricular level.

To summarize these observations, the presence of left ventricular enlargement differentiates shunts distal to the AV valves from those at the atrial level, and the presence of aortic enlargement differentiates shunts distal to the aortic valve from those at the ventricular level.

Associated valvular deformities modify these findings. Furthermore, combinations of anomalies, such as ventricular septal defect plus patency of the ductus or coarctation of the aorta, occur with sufficient frequency that one cannot expect to reach an exact anatomic diagnosis each time from radiologic studies. Each series of films, however, is a new challenge to detect the changes present and to offer the most reasonable explanations for the observed manifestations.

the barium curves to the right below the diaphragm to enter a stomach that is also in the right upper quadrant.

In the LAO projection, the barium mixture falls straight down, without indentation by structures in front or behind (Fig. 6-51).

In the RAO view, the barium column curves posteriorly about the left aortic arch and then hugs the back of the heart as it descends in a straight line, without indentation, toward the stomach (Fig. 6-51). In infancy, the aorta as it arches may impinge very little on the esophagus. One then identifies the left aortic arch because there is evidence of a left descending aorta and no retroesophageal vessels.

The structures which cause any departure from the above course of the esophagus are the aorta, or some of its branches, and the left atrium. Neither the right atrium nor right or left ventricle is in contact with the esophagus and, therefore, cannot alter the esophagram.

One of the common aortic anomalies is a *right aortic arch and descending aorta*. This can occur as an isolated abnormality or in association with other cardiac anomalies. It is found in about 25 per cent of patients with a tetralogy of Fallot. Persistence of the right aortic arch gives a mirror image of the normal course of the aorta and a mirror image of the normal esophagram. In frontal view, the barium curves to the left at the level of the right aortic arch, and it descends to the left of the midline, where it is displaced by the *right descending aorta* (Fig. 6-69A). In the LAO projection, the barium curves posteriorly at the level of the arch, and in the RAO view, it falls freely without indentation. Rarely does the aorta pass behind the esophagus before arching to the right.

Sometimes the aorta arches to one side, then crosses over high in the thorax and descends on the opposite side. If it does so, the side of the arch is identified by the direction it displaces the esophagus in the frontal and oblique projections, as described above. Then the esophagus kinks abruptly or obliquely in the frontal view as the aorta crosses behind it, and in the oblique projections, the esophagus curves forward around the retroesophageal aorta. The side on which the aorta descends is identified in the frontal view by whether the barium descends in the midline (left descending aorta) or to the left

of the midline. One can also visualize the descending aorta if the patient is turned into the oblique projection corresponding to the side on which the aorta descends, e.g., RAO for right-sided descending aorta.

Here is an illustration of such an analysis: if the barium curves to the right in the frontal and RAO views, there is a left aortic arch. A large forward bowing of the esophagus just below the level of the aortic arch indicates a retroesophageal course of the aorta, and the descent of the barium column in frontal view to the left of the midline confirms the fact that the aorta has crossed over to descend on the right side (Fig. 6-68).

A similar analysis holds for patients with a *vascular ring* and a *double aortic arch* (Fig. 6-68). Each component is identified by the manner in which it affects the esophagus. However, if one part of the ring is hypoplastic or a ligament, then the presence of only the well-developed arch and a retroesophageal vessel will be manifest.

Other aortic arch anomalies recognizable by changes in the esophagram produce a forward displacement of the esophagus in one or both oblique views because of their retroesophageal location. These include *aberrant right subclavian artery* (Fig. 6-69B), *anomalous vessels* of collateral circulation from aorta to lungs (Fig. 6-69C), and *coarctation of the aorta* (Fig. 6-66).

Aberrant right subclavian artery comes off below the left subclavian artery as the last of the brachiocephalic vessels, and it crosses behind the esophagus and obliquely upward to enter the right arm. Thus in the oblique projections the esophagus is pushed forward, and in the frontal view there is an *oblique filling defect*, low on the left and high on the right side (Fig. 6-69B). Aberrant subclavian artery has been associated with *dysphagia lusoria*, but in the pediatric age group symptoms are rare.

Anomalous vessels from the aorta to the lungs alter the barium swallow when they come off the descending aorta and pass behind the esophagus to anastomose with the pulmonary arteries. These collaterals may be single or multiple, and if of sufficient size, they indent the esophagus on its posterior aspect and can be identified in oblique or lateral views (Fig. 6-69C).

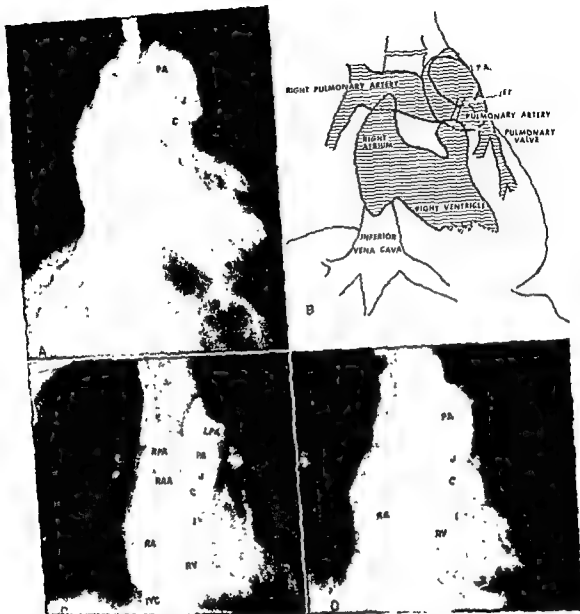

Fig 6-71. A. Isolated valvular pulmonic stenosis in a 22-year-old woman with pressures of 194/8 mm Hg in the right ventricle and 13/3 in the pulmonary artery. A frontal angiocardiogram, 2½ sec after the beginning of injection shows the infundibulum (I) of the right ventricle to be widely patent. The pulmonic cusps (C) are clearly outlined, and the jet (J) entering the poststenotic pulmonary artery (PA) is evident. The peripheral pulmonary vascular tree is markedly decreased. B. Tracing of (A). C. Isolated pulmonic valvular stenosis in a 27-year-old woman with pressures of 175/25 mm Hg in the right ventricle and 25/5 in the pulmonary artery. The right atrium (RA), inferior vena cava (IVC), right ventricle (RV), infundibulum (I), pulmonic cusps (C), pulmonary artery (PA), right (RPA) and left (LPA) branches of the pulmonary artery are opacified. Note the jet (J) directed into the poststenotic dilated pulmonary artery. The infundibulum is in systole; its contracted state simulates stenosis. The peripheral pulmonary arterial tree is diminished. D. Valvular pulmonic stenosis and atrial septal defect in a 34-year-old woman with arrested pulmonary tuberculosis. Right ventricular hypertension, 96/15; pulmonary artery mean pressure, 10 mm Hg. The right atrium (RA) is in diastole; the right ventricle (RV) with its outflow tract, the infundibulum (I), is also contracted because of systole. Note the pulmonic cusps (C) with the jet (J) streaming into the poststenotic pulmonary artery (PA). The pulmonary vasculature is markedly decreased. The narrowed infundibulum simulates stenosis. Other films demonstrated right-to-left shunt through an atrial defect.

but with a normal-appearing heart and great vessels. From the patient's standpoint, this is probably a favorable situation, meaning that his lesion is so mild it has not altered cardiac dynamics enough to make its presence felt. But from the point of view of the physician interested in a diagnosis, this can be frustrating. Small patent ductus, small ventricular septal defect, slight pulmonic or aortic stenosis, etc., are among the possibilities.

If there is enlargement of some chamber or vessel, one has more to go on. It is helpful then to decide how far the enlargement extends to the structures proximal and distal to the one involved. For example, if the right atrium is prominent and the right ventricle is enlarged, one analyzes the pulmonary arteries and left side of the heart for evidence of involvement. If the main pulmonary artery is then found to be enlarged, but the pulmonary artery branches are not and the left side of the heart is normal, this points to *calcular pulmonic stenosis* with poststenotic dilatation of the main pulmonary artery and with enlargement of the right side of the heart as a result of the obstruction (Fig. 6-38). If not only the main pulmonary artery but also the branches throughout the lung fields are found engorged and actively pulsating while the left side of the heart is normal, this implies a lesion producing *overcirculation* through the right heart chambers and pulmonary vascular tree, an atrial septal defect, an anomalous pulmonary venous drainage, or both (Fig. 6-61).

If in addition to enlargement of the right heart chambers, main pulmonary artery, and branches, there is moderate enlargement of the left atrium but not of the left ventricle (a point sometimes difficult to determine), *mitral valvular obstruction* is implicated.

If the enlargement includes the left ventricle besides, but the aorta is normal or small, several possibilities are suggested. For instance, a lesion of the mitral valve with insufficiency and often also with stenosis, or endocardial or myocardial involvement of the left ventricle with secondary changes in the lungs and right heart, as in *endocardial fibroelastosis*, *myocarditis*, *anomalous origin of the left coronary artery*, or *glycogen storage disease of the heart*. If the pulmonary arterial engorgement is noteworthy and pulsations of the vessels are in-

creased, *ventricular septal defect* is likely (Fig. 6-62).

If the enlargement involves the aorta, in addition to the chambers and vessels proximal to it, this places the lesion at the aortic valve or beyond, e.g., *aortic stenosis*, *insufficiency*, or both or *coarctation of the aorta* (Figs. 6-66 and 6-67). If there is pulmonary overcirculation, then *patent ductus arteriosus* (or the rare aortic septal defect) is the probable diagnosis (Fig. 6-63).

Patients with left-to-right shunts producing increased pulmonary blood flow present a frequent problem in differential diagnosis of the site of the shunt. The accompanying schematic diagram (Fig. 6-60) illustrates some useful points in differentiation if the shunt is large enough to cause a detectable change in chamber and vessel size. The electrocardiographic expression of ventricular hypertrophy or dilatation is shown alongside the appropriate ventricle. Particularly for infants in difficulty because of the large left-to-right shunt, these differential features have been useful.

For comparison, the normal situation is illustrated at the upper left, where each side of the heart carries the same volume of blood and the internal dimensions of chambers and vessels are comparable on the two sides. The thickness of the two ventricles is the chief difference, a reflection of the differences in peripheral resistances in the pulmonary and systemic circuits.

In the other three conditions, the pulmonary blood flow is increased above normal by the left-to-right shunt, and the pulmonary artery is enlarged in all. It is what happens to this increased volume of blood after it returns from the lungs that determines the changes to be described.

When the shunt is at the atrial level, a large portion of the blood coming to the left atrium passes across the defect into the right atrium and a smaller amount takes the normal route across the mitral valve to the left ventricle. The disproportionate division is believed related to the greater distensibility of the right atrium and right ventricle, which offer less resistance to flow than do the more tense left atrium and left ventricle. If there is *anomalous pulmonary venous drainage* from the lungs, the right atrium (directly or through one of its tributaries) receives a supernormal

were markedly enlarged. In two patients with a patent ductus arteriosus, there was left atrial enlargement, enlargement of the pulmonary artery and right ventricle, with reversal of flow through the ductus due to pulmonary hypertension.

**Coarctation of the Aorta.** Angiocardiography in coarctation of the aorta is customarily performed in the LAO projection, which affords an open view of the aortic arch similar to surgical exposure. The angiographic findings are as follows. The left ventricle may be enlarged. The ascending aorta, often normal in young patients, is usually dilated in the adult. The innominate and left subclavian arteries are often markedly dilated, the left common carotid artery is moderately enlarged. Collateral channels, particularly the internal mammary and shoulder girdle arteries, are markedly dilated and tortuous. The intercostal arteries are not as well visualized. The exact site of coarctation is readily identified at a variable distance beyond the left subclavian artery (Fig 6-73A). There is an area of abrupt constriction which is obscured in part by overlapping of the poststenotic segment of the aorta. The diameter of the lumen at the site of coarctation cannot be determined. Prompt filling of an aorta distal to the stenosis may occur via collaterals in the absence of any opening. The length of the stub of aorta distal to the left subclavian artery and proximal to the site of stricture varies, ranging between no stub to a 4.5-cm segment. Dilated intercostal arteries may occasionally be seen connecting with the poststenotic descending aorta. Occasionally aneurysms of the intercostal vessels can be recognized. Poststenotic aortic dilatation varies greatly and is generally more marked in older patients; the lower thoracic aorta is usually small.

Aneurysmal dilatation of the aortic sinuses associated with coarctation of the aorta has been recognized. Pseudocoarctation, a congenital type of kinking of the aorta, closely resembles coarctation of the aorta. Indeed, the angiographic studies may duplicate the

findings seen in coarctation of the aorta. The differentiation from a true coarctation depends upon the absence of arterial collaterals and normal lower extremity blood pressures (Steinberg, 1956).

## SIMPLE SHUNTS

**Atrial Septal Defects.** The angiogram reveals right heart and pulmonary arterial enlargement. Contrast agents can sometimes be seen to pass from the right to the left atrium. Filling defects due to left-to-right shunting of blood may often be recognized in the right atrium. Associated defects such as pulmonary stenosis, tricuspid atresia, and anomalous drainage of pulmonary veins are frequently accompanied by right-to-left atrial shunts. The usual finding is that of persistent opacification of the right atrium, right ventricle, and pulmonary arteries which lasts during the entire period of cardiac filling and results from recirculation of opacified blood from the left to the right atrium. Opacification of the chambers of the left heart and aorta is usually of poor quality because of dilution of the contrast agent by large volumes of shunted blood. Persistent opacification of the pulmonary arteries also occurs as a result of a large ventricular septal defect, patent ductus arteriosus, and defects in the aortopulmonary septum, but the right atrium does not share in the opacification. It is occasionally difficult to establish with certainty that recirculation of contrast agent is actually present. A slow injection or the trapping of contrast agent in the arm or neck veins may result in prolonged filling of the right atrium and lead to a mistaken angiographic diagnosis of atrial defect.

**Ventricular Septal Defects.** Angiocardiography may show no abnormality in the presence of small defects in the ventricular septum. There may be evidence of recirculation of the right ventricle (but not the right atrium) at the time of left heart filling, but as is a case with atrial defects, the finding is difficult to evaluate. In high ventricular septal defects there may be angiographic demonstra-

90/72, has had severe precordial pain for 10 years. The left ventricle (LV) is moderately enlarged. The ascending aorta is markedly dilated and measures 50 mm in the mid-ascending portion (average normal, 28 mm). There is also moderate dilatation of the brachiocephalic arteries (A, innominate, ICC, left common carotid, LSA, the left subclavian arteries).

ISRAEL STEINBERG

## STENOSIS OF A VALVE OR VESSEL

**Pulmonic Stenosis.** There are two main types of pulmonary stenosis, the valvular and infundibular. The *valvular* types (Fig 6-71) consist of a dome-shaped membranous opened, umbrella-like structure formed by the fused pulmonic cusps. An orifice, usually centrally located, can be identified by a "jet" of opacified blood. The valve cusps are mobile despite fusion and are easily identified, especially during diastole. The right ventricle is enlarged, and during diastole, thickening and trabeculation of the wall can be recognized (Fig 6-71). The outflow tract of the right ventricle is of good caliber during systole (Fig. 6-71) but may appear contracted and simulate infundibular stenosis during diastole. The main stem pulmonary artery has often a characteristic *poststenotic dilatation* (Fig 6-71). The peripheral branches may be normal but are usually reduced in size. *Supra-valvular pulmonic stenosis* is rare (Fig. 6-72A). *Multiple stenosis of the pulmonary arteries*, chiefly the main branches, has recently been reported and called "coarctation of the pulmonary arteries."

**Infundibular stenosis** of the pulmonary artery rarely occurs as an isolated lesion. Usually it is associated with deformities of the ventricular septum, occurring in the tetralogy of Fallot and in transposition.

**Aortic Stenosis.** Aortic stenosis may be divided into the valvular and subvalvular types.

In the *valvular* types, the cusps are thickened and may be fused to form a dome-shaped diaphragm with a central opening. Frequently, there is *poststenotic dilatation* of the ascending aorta. Whether valvular stenosis is here a truly developmental anomaly or is the result of endocardial fibroelastosis is difficult to decide clinically (Nadas). It is almost impossible to distinguish between aortic valvular and subaortic types, even after angiocardiography. Figures 6-72C and 6-73A, B show dome-shaped deformities of the aortic cusps with poststenotic dilatation of the ascending aorta. Figure 6-72B shows the angiocardiogram of a puppy who had all the physical signs of aortic stenosis; the diagnosis was confirmed at operation. The angiocardiograms of congenital aortic valvular stenosis in a child (Fig. 6-72C) and in an adult (Fig 6-72D) are also illustrated.

**Mitral Stenosis.** Congenital mitral stenosis is rare, but associations with aortic valve, aorta, and ductus arteriosus malformations are not uncommon (Ferencz et al.). In the angiocardiogram, isolated enlargement and delay in emptying of the left atrium, and enlargement of the right ventricle and pulmonary artery are seen in uncomplicated mitral stenosis. In one patient who had partial anomalous drainage from the right lung into the superior vena cava and an atrial septal defect (Lutembacher's syndrome), the left atrium was hypoplastic and the pulmonary arteries, pulmonary vascular tree, and right ventricles

tion of shunting of blood in both directions across the defect, especially with pulmonary hypertension. Even after cardiac catheterization, it may be difficult in certain cases to distinguish between such a lesion and the Eisenmenger complex.

**Patent Ductus Arteriosus.** The angiographic findings which have been observed in patients with patent ductus arteriosus include (1) dilation of pulmonary arteries, (2) high position of the left pulmonary artery, (3) a defect in the column of contrast substance within and at the time of filling of the pulmonary artery and left pulmonary artery caused by a "jet" of nonopacified blood issuing from the ductus (Fig 6-73B), (4) persistent opacification of the pulmonary arteries at the time of aortic filling (Fig 6-73C), (5) localized dilatation of the aorta at the site of origin of the ductus, and (6) rarely, opacification of the ductus itself. These signs have all been absent in some proved cases of patent ductus arteriosus. Thoracic aortography reveals the anatomy of patent ductus arteriosus with clarity (Kjellberg et al, 1955), but its routine use is not justified since the diagnosis can usually be established by the stethoscope.

In some cases of patent ductus, the pulmonary arterial blood pressure may be elevated to systemic levels. When this occurs, the direction of flow across the ductus becomes reversed, with the production of typical clinical and angiographic findings. As illustrated in Fig 6-73B, early opacification of the descending (but not the ascending) aorta occurs. Later films show opacification of the ascending aorta and rule out the presence of stenosis of the aortic arch. As would be expected, this situation results in cyanosis localized to the lower but not the upper extremities (Lukas et al).

**Aortic Septal Defect.** Since patent ductus and aortoseptal defects produce the same hemodynamic abnormality, it is usually not

possible to distinguish them by means of angiocardiology. Fortunately, the latter lesion is rare. The diagnosis may be suspected clinically and confirmed by thoracic aortography. Such a defect has been occasionally repaired, although in general it must be considered an inoperable condition.

## COMBINED MALFORMATIONS

**Pulmonic Stenosis plus Atrial Septal Defects.** In the presence of a combined pulmonary stenosis and a defect in the atrial septum, an overriding aorta may be simulated on angiocardiology. In this malformation, blood passes across the septal defect from the right to the left atrium, via the left ventricle into the aorta, while at the same time blood entering the right ventricle through the tricuspid valve reaches the lungs through a stenotic pulmonary artery. Cyanosis results. Angiocardiology may reveal simultaneous opacification of the aorta and the pulmonary artery. The diagnosis of dextroposition of the aorta is made less likely by the demonstration of a direct passage of contrast agent from the right to the left atrium on early films of the series. This finding is not conclusive since an atrial defect with reversal of flow may sometimes complicate the tetralogy of Fallot. Reflux of contrast agent into the inferior vena cava is common in this condition as in tricuspid stenosis or atresia but may also occur normally. In pulmonary stenosis and atrial septal defect, the pulmonary arteries usually show poststenotic dilation and are emptied of contrast substance more slowly than is the aorta. Especially, when the pulmonary stenosis is severe, cyanosis may be present from birth. In other cases, cyanosis may be delayed in onset. This is because the pulmonary stenosis over a period of years has resulted in a gradual elevation of the right ventricular end-diastolic and hence the right atrial pressure. When the latter exceeds the pressure in the left atrium,

reopacification (arrow) of the left pulmonary artery. D Frontal angiogram of a 4-month-old infant with cyanosis of the lower trunk and extremities and murmurs of aortic stenosis. When the right heart structures—right atrium (RA), right ventricle (RV), pulmonary artery (PA)—were opacified, there was reversed blood flow through a patent ductus arteriosus (white arrow) into the descending aorta (AO). The abdominal aorta (black arrow) contains unsaturated pulmonary arterial blood and is responsible for the lower trunk and extremity cyanosis. Ligation of the ductus resulted in improvement for 3 days. Death was sudden. At necropsy, fibroelastosis of the left ventricle with aortic stenosis was found.

Fig. 6-72. A. Stenosis of right pulmonary artery in a 4-year-old child, with pulmonic valvular stenosis. Cardiac catheterization showed right ventricle pressure of 60/6, pulmonary artery (mean) pressure, 10 mm Hg. There was no pressure change on withdrawal of the catheter from the right pulmonary artery. However, stenosis (arrow) of the right pulmonary branch is clearly seen in the angiogram. B. Aortic valvular stenosis, confirmed by operation, in a 4-month-old German shepherd dog. Note the dome-shaped aortic cusps (arrow) with the poststenotic ascending aorta (AO). C. Valvular stenosis in a 9-year-old boy with a history since birth of a systolic murmur transmitted to the neck. The left atrium (LA) and left ventricle (LV) are opacified. Note the deformed aortic cusps (arrow) and the poststenotic dilated ascending aorta (AO) which measures 4 cm in diameter (normal 25 mm). Previous angiogram 3 years earlier also showed deformed aortic cusps and poststenotic dilatation of the aorta. D. Valvular aortic stenosis in a 27-year-old woman with a history of an aortic systolic murmur since birth. Blood pressure is

Angiocardiography, by showing marked lateral displacement of the tricuspid valve membrane, often establishes the diagnosis. Usually there is a slight notch along the inferior border of the heart well toward the left cardiac silhouette (Fig. 6-74A). Marked dilatation of the right atrium and the proximal portion of the right ventricle forming a common chamber may also be detected. The atrialized portion of the ventricle may also be markedly thinned. Prolonged opacification of the right cardiac chamber is usual, with hypoplasia of the main pulmonary artery and its stems. The peripheral pulmonary arterial tree is strikingly decreased and poorly opacified (Fig. 6-74A). In about 60 per cent of the cases, right-to-left filling of the atria can be demonstrated, indicating either a patent foramen ovale or an atrial septal defect.

**Mitral Stenosis plus Atrial Septal Defect (Lutembacher's Syndrome).** The combination of rheumatic mitral stenosis with an atrial septal defect (Lutembacher's syndrome), while uncommon, is not so rare as the congenital type of mitral stenosis with atrial septal defect. In one case, angiocardiography revealed a "jet sign" at the insertion of the anomalous veins of the right lung and demonstrated an atrial septal defect but failed to detect the mitral stenosis; hypoplasia of the left atrium was in marked contrast to the usual enlargement of this structure.

## COMPLEX MALFORMATIONS

**Tetralogy and Pentalogy of Fallot.** Tetralogy of Fallot consists essentially of the combination of two lesions, pulmonary stenosis (infundibular or valvular) and dextroposition or overriding of the aorta. A physiologic, if not an anatomic, ventricular septal defect always occurs when the aorta overrides the ventricular septum, while right ventricular hypertrophy is the result of pulmonary stenosis.

The angiocardiographic identification of pulmonary stenosis may be direct or indirect. Selective angiocardiography has considerably increased the direct diagnosis of pulmonary stenosis (Kjellberg et al., 1955). In only about half the cases, the pulmonary infundibular or valvular narrowing is seen with the intravenous method. The presence of stenosis may, however, be inferred with reasonable assurance

from one or more of the following findings: (1) the peripheral pulmonary arteries are unusually small; (2) they fill poorly with opaque substance; and (3) the central pulmonary arteries, even though fairly large and well filled, are irregularly deformed in appearance, while the peripheral branches are disproportionately small. Even though good filling of apparently normal pulmonary arteries is seen, pulmonary stenosis cannot be excluded angiocardiographically (although in such cases it is reasonable to conclude that marked reduction in pulmonary blood flow is not present). Furthermore, failure of the pulmonary arteries to fill with contrast substance may be the result of transposition of the great blood vessels rather than pulmonary stenosis.

**Dextroposition or overriding of the aorta** is manifest in the angiocardiogram by the immediate passage of contrast agent from the right ventricle into the aorta, a direct demonstration of the cause of the patient's cyanosis. In general, the degree to which the aorta overrides can be estimated from two findings. If early aortic opacification is faint as compared to the density in the pulmonary artery and as compared to that obtained later in the angiocardiographic series when contrast substance reaches the aorta from the left ventricle, it may be assumed that but slight dextroposition exists. Furthermore, the position of the base of the aorta with respect to the heart border and the contour of the aortic arch are of significance. The farther anterior the origin of the aorta and the more rounded out its course throughout the thorax, the greater is the degree of aortic overriding (Fig. 6-74B).

The so-called *pseudotruncus arteriosus* is a variant of the tetralogy of Fallot in which the pulmonary artery is markedly stenotic if not atretic, circulation to the lungs being via bronchial arteries.

Angiocardiography readily demonstrates associated anomalies of the aortic arch and branches. A right aortic arch and the position of the branches may be often a determining factor in the type of aortopulmonary surgery, i.e., whether the Potts or Blalock-Taussig operation is done (Cooley et al., 1949).

**Pentalogy of Fallot.** In the pentalogy of Fallot, the angiocardiographic findings are essentially as in the tetralogy, with the addition of an atrial septal defect. This is demonstrated

Fig. 6-72. A Stenosis of right pulmonary artery in a 4-year-old child, with pulmonic valvular stenosis. Cardiac catheterization showed right ventricle pressure of 60/6; pulmonary artery (mean pressure, 10 mm Hg. There was no pressure change on withdrawal of the catheter from the right pulmonary artery. However, stenosis (arrow) of the right pulmonary branch is clearly seen in the angiogram. B, Aortic valvular stenosis, confirmed by operation, in a 4-month-old German shepherd dog. Note the dome-shaped aortic cusps (arrow) with the poststenotic ascending aorta (AO). C, Valvular stenosis in a 9-year-old boy with a history since birth of a systolic murmur transmitted to the neck. The left atrium (LA) and left ventricle (LV) are opacified. Note the deformed aortic cusps (arrow) and the poststenotic dilated ascending aorta (AO) which measures 4 cm in diameter (normal 35 mm). Previous angiogram 3 years earlier also showed deformed aortic cusps and poststenotic dilatation of the aorta. D Valvular aortic stenosis in a 27-year-old woman with a history of an aortic systolic murmur since birth. Blood pressure is

pulmonary artery partially overrides the ventricular septum. A high ventricular septal defect and right ventricular hypertrophy complete the syndrome (Chiechi). The diagnostic angiocardiographic feature consists of simultaneous filling of the dilated pulmonary artery and aorta, differentiating it from the ordinary transposition. However, this is not pathognomonic since transposition with a large ventricular septal defect can produce the same picture. Outlining the ventricular septum with

a clear origin of the pulmonary artery from both ventricles and transposition of the aorta are essential for diagnosis of the Taussig-Bing complex.

**Tricuspid Atresia.** In tricuspid atresia, blood flow is from the right atrium across an atrial defect into the left ventricle and then into the aorta and pulmonary arteries, often via a ventricular septal defect into a rudimentary pulmonary conus. The origin of the great vessels may vary considerably. Both may arise

**Fig 6-76** Tricuspid atresia and pulmonary stenosis in a 3-year-old child (verified at autopsy). **A**, Frontal angiocardiogram showing early filling of the right atrium (RA) from the superior vena cava (SVC). The inferior vena cava (IVC) is filled refluxly. **B**, Shortly thereafter, there is filling of the left atrium (LA) and left atrial appendage (LAA). Arrow points to the hypoplastic right ventricle. **C**, Later, the left atrium (LA), left ventricle (LV), aorta (AO), and pulmonary artery (PA) are opacified. The deformed and poorly filled pulmonary artery and branches (arrow) are indications of decreased pulmonary blood flow. **D**, The early lateral angiocardiogram shows opacification of the right atrium (RA), superior vena cava (SVC), inferior vena cava (IVC), and left atrium (LA). **E**, Later, there is filling of the aorta (AO) and left ventricle (LV). The pulmonary artery is vaguely outlined and the pulmonary vasculature is markedly decreased. **F**, Frontal angiocardiogram of a 5-month-old cyanotic infant with mitral atresia (verified at autopsy) reveals simultaneous filling of the right atrium (RA), right ventricle (RV), pulmonary artery (PA), and aorta (AO). The unfilled left lower cardiac shadow (arrow) represents the nonfunctioning rudimentary left ventricle. Death at autopsy. The opacified descending aorta was apparently filled from the pulmonary artery by reversed flow through the ductus.

Fig. 6-73. A. Left anterior oblique angiogram in a 24-year-old woman with mild hypertension (142/80) of the upper and hypotension (75/0) of the lower extremities. The left ventricle (LV) is normal in size. The ascending aorta (AO) is mildly dilated. The brachiocephalic arteries—the innominate (IA), left common carotid (LCCA) and the left subclavian (LSA)—are only slightly dilated, operation was postponed. B. Frontal angiogram shows the opacified right heart. A tiny rounded area (arrow) in the left pulmonary artery is a "jet" of unopacified blood from a patent ductus arteriosus. C. When the left heart chambers, left atrium (LA), left ventricle (LV), and aorta (AO) are opacified, there is

pulmonary artery partially overrides the ventricular septum. A high ventricular septal defect and right ventricular hypertrophy complete the syndrome (Chenchi). The diagnostic angiocardigraphic feature consists of simultaneous filling of the dilated pulmonary artery and aorta, differentiating it from the ordinary transposition. However, this is not pathognomonic since transposition with a large ventricular septal defect can produce the same picture. Outlining the ventricular septum with

a clear origin of the pulmonary artery from both ventricles and transposition of the aorta are essential for diagnosis of the Taussig-Bing complex.

**Tricuspid Atresia.** In tricuspid atresia, blood flow is from the right atrium across an atrial defect into the left ventricle and then into the aorta and pulmonary arteries, often via a ventricular septal defect into a rudimentary pulmonary conus. The origin of the great vessels may vary considerably. Both may arise

A. Frontal angiocardiogram showing early filling of the right atrium (RA) from the superior vena cava (SVC). The inferior vena cava (IVC) is filled reflexly. B. Shortly thereafter, there is filling of the left atrium (LA) and left atrio-

tricle. C. Later, the left atrium (LA),

opacified. The deformed and poorly

of decreased pulmonary blood flow. D. The early lateral angiocardiogram shows opacification

of the right atrium (RA), superior vena cava (SVC), inferior vena cava (IVC), and left atrium (LA).

E. Later, there is filling of the aorta (AO) and left ventricle (LV). The pulmonary artery is vaguely

outlined and the pulmonary vasculature is markedly decreased. F. Frontal angiocardiogram of a

3-month-old cyanotic infant with mitral atresia (verified at autopsy) reveals simultaneous filling of

the right atrium (RA), right ventricle (RV), pulmonary artery (PA), and aorta (AO). The unfilled left

lower cardiac shadow (arrow) represents the nonfunctioning rudimentary left ventricle. Death

from heart failure ensued, and a patent ductus arteriosus and coarctation of the aorta were found

at autopsy. The opacified descending aorta was apparently filled from the pulmonary artery by

reversed flow through the ductus.

reversed flow across the defect (usually a patent foramen ovale) occurs and cyanosis results.

**Aortic Stenosis plus Coarctation of the Aorta or Patent Ductus Arteriosus.** The occurrence of aortic stenosis and a patent ductus arteriosus or coarctation of the aorta is uncommon. In a patient with fibroelastosis of the left ventricle and aortic valvular stenosis, the angiogram showed a markedly enlarged left ventricle (cavity and wall) with delay in emptying. There was also marked dilatation of the ascending aorta, which terminated abruptly beyond the left subclavian artery and simulated coarctation of the aorta. Caution is advised in making the diagnosis of coarctation of the aorta in the presence of aortic stenosis unless there is unequivocal clinical evidence of coarctation, such as the corroborative findings of diminished or absent femoral arterial blood flow. Reversal of flow through a patent ductus resulted when fibroelastosis of the heart and aortic stenosis were associated with marked pulmonary hypertension (Fig 6-73D).

**Tricuspid Insufficiency (Ebstein's Anomaly).** Ebstein's anomaly consists of fusion of the tricuspid leaflets into a membranous structure extending into the cavity of the right ventricle, forming proximal and distal chambers. The proximal chamber becomes continuous with the right atrium; the distal chamber functions as the right ventricle. An atrial septal defect, either a patent foramen ovale or true atrial septal defect, may also be present and cause cyanosis. Usually the wall of the proximal portion of the ventricle (the atrialized chamber) is thinned. The rest of the ventricle is often hypertrophied.

artery and branches are hypoplastic and unopacified. B Frontal angiogram of a 5½-year-old child with tetralogy of Fallot. The classical features of the complex are readily seen. There is simultaneous opacification of the pulmonary artery (PA) and aorta (AO). The right ventricle (RV) is large, the infundibulum (I) is stenotic (arrow), and there is poststenotic dilatation of the pulmonary artery with diminished pulmonary vasculature, especially within the right lung. C Frontal angiogram of a 4-month-old infant with complete transposition of the great vessels, confirmed at autopsy. The right atrium (RA) is normal in size. The right ventricle (RV) is large, and the aorta (AO) is seen arising from it.

Fig. 6-74. A. Frontal angiogram of a 19-year-old woman with Ebstein's anomaly (confirmed by cardiac catheterization). The superior vena cava (SVC) is widened; the right atrium (RA) is huge, and the right ventricle (RV) is divided at the notch (arrow), the site of the tricuspid membrane, into proximal and distal chambers. The outflow tract of the right ventricle is poorly defined; and the pulmonary

Fig. 6-77. Upper left, congenital absence of the right pulmonary artery. Frontal angiocardiogram of an asymptomatic 24-year-old man shows opacification of the superior vena cava (SVC), right atrium (RA), right ventricle (RV), infundibulum (I), pulmonary artery (PA), and left pulmonary artery (LPA). The right pulmonary artery is congenitally absent. A later film at the time of aortic opacification revealed a fine lacelike pattern of pulmonary vasculature in the right lung, presumably coming from bronchial arteries. Upper right, frontal angiocardiogram of a 24-year-old asymptomatic man with congenital absence of the left pulmonary artery. The right ventricle (RV), pulmonary artery (PA) and right pulmonary artery (RPA) are opacified. The left pulmonary artery is congenitally absent. Later, the left lung became opacified from bronchial arteries. Lower left, agenesis of the left lung with reversal of blood flow through a patent ductus arteriosus in a 22-year-old man. Angiocardiogram shows the enlarged right ventricle, pulmonary artery with the patent ductus arteriosus, and opacified descending aorta. The left pulmonary artery is absent. Lower right, tracing of (A).

by right-to-left flow from the right to left atrium.

**Eisenmenger's Complex.** In this anomaly, there is an overriding aorta associated with pulmonary hypertension. Angiocardiographically, the overriding aorta and pulmonary artery are often filled simultaneously from the right ventricle. However, with a slight degree of overriding the aorta may be only faintly filled. The differential diagnosis between Eisenmenger's complex and a high ventricular septal defect is made with great difficulty, even after cardiac catheterization. Marked enlargement of the main trunk of the pulmonary artery and dilatation of the pulmonary and peripheral branches with dense opacification are usually present (Ebnotha and Abrams).

**Transposition of the Great Blood Vessels.** It may be difficult to distinguish with certainty between extreme dextroposition of the aorta associated with severe pulmonary stenosis and complete transposition of the aorta and pulmonary artery, particularly when pul-

monary stenosis complicates transposition. The aorta in transposition "takes off" far anteriorly and describes an open, rounded course through the upper thorax (Figs. 6-74C and 6-75). The density of contrast substance within the aorta closely approximates that within the right ventricle (Fig. 6-74C). If the pulmonary arteries appear prominent in the conventional roentgenogram or unusually pulsatile at fluoroscopy and yet fill poorly or not at all during angiocardiography, transposition of the aorta and pulmonary artery should be strongly suspected (Fig. 6-75). When pulmonary stenosis is present, the diagnosis may be more difficult. Although, in transposition of the great blood vessels, life is dependent upon some intercommunication between the systemic and pulmonary circuits, these communications are rarely demonstrated by angiocardiography.

**Taussig-Bing Syndrome.** In this anomaly, a transposed aorta and a large pulmonary artery arise primarily from the right ventricle; the

Fig. 6-75. Complete transposition of the great vessels in a 2-year-old infant. A Frontal angiocardiogram shows the right heart, superior vena cava (SV), right atrium (RA), and right ventricle (RV) opacified. The aorta (O) arises from the right ventricle. B Lateral angiocardiogram reveals the right heart structures, the superior vena cava (SVC), right atrium (RA), and right ventricle (RV). The aorta (AO) arises from the right ventricle and sweeps forward just behind the sternum and arches posteriorly to descend well along the spine. Later, poor filling of the pulmonary artery arising from the left ventricle was recognized.

Fig. 6-79 A Frontal an-

age of the right pulmonary artery (PA), left ventricle (LV), and aorta (AO); there was no evidence of the right pulmonary veins. B. Total anomalous pulmonary venous drainage into the left innominate vein in a 42-year-old woman. There is a filling defect (arrow) in the left innominate vein (LIV) due to a stream of blood from the anomalous pulmonary veins. The right superior vena cava (SVC) is markedly dilated and forms a right mediastinal mass. The right atrium (RA), right ventricle (RV), and pulmonary artery are also enlarged. C. Later, the pulmonary veins in both lungs form a common channel (arrow) which inserts into a huge structure, probably a persistent left superior vena cava (PLSVC) which is responsible for the left superior mediastinal mass. D. Total anomalous pulmonary venous drainage of pulmonary veins into the junction of the superior vena cava and right atrium in a 16-year-old girl. There is a filling defect (arrow) at the junction of the superior vena cava (SVC) and right atrium (RA) caused by a "jet" of unopacified blood from pulmonary veins. The right ventricle (RV) and pulmonary artery (PA) are enlarged.

from the left ventricle; either may arise from a diminutive right ventricle which receives blood from the left ventricle via a ventricular septal defect. Pulmonary stenosis may occur, as may an associated patent ductus arteriosus (Cooley et al., 1950). Angiocardiography usually reveals the abnormal course of blood flow clearly (Fig. 6-76). In this example the aorta takes origin from a diminutive, nonfunctioning right ventricle (filled via an interventricular septal defect), while the small pulmonary arteries give evidence of pulmonary stenosis. In another case (Dotter and Steinberg, 1951), tricuspid atresia was associated with dextrocardia, a common atrium, an anomalous pulmonary vein entering a left superior vena cava, a functioning single ("left") ventricle, severe pulmonary stenosis, and a large patent ductus through which blood reached the lungs. All the anatomic features, except the tricuspid atresia, were clearly shown in the angiocardiogram. Since the diagnosis of tricuspid stenosis or atresia may be considered likely when cyanosis and left axis deviation occur together, angiocardiography need be employed only when surgical procedures are contemplated or in atypical cases.

**Mitral Atresia plus Patent Ductus and Coarctation of the Aorta.** A cyanotic infant showed (Fig. 6-76F) almost immediate filling of the right heart and aorta. At autopsy there was mitral atresia, coarctation of the aorta, and a patent ductus arteriosus. The angiocardiogram was striking because all the cardiovascular structures, save the functionless hypoplastic left ventricle, were opacified, the patent ductus could not be recognized with certainty.

## ANOMALIES OF THE LARGE ARTERIAL VESSELS

**Primary Dilatation (Aneurysm) of the Pulmonary Artery.** Idiopathic or primary dilatation of the pulmonary artery is rare. Angiocardiography readily demonstrates enlargement of the pulmonary artery. However, the diagnosis of primary dilatation of the pulmonary artery can be made only when the many causes of pulmonary artery dilatation, such as pulmonic stenosis, congenital heart disease, rheumatic heart disease, cor pulmonale, heart failure, and syphilis, are excluded. Primary dilatation without hypertension rarely causes disability and requires no treatment.

**Absence of a Main Stem of the Pulmonary Artery.** Either a right or left main stem of the pulmonary artery may be congenitally absent, and the diagnosis can often be made by conventional roentgenography. There is displacement of the mediastinum (mediastinal herniation), trachea, and heart by an overdistended lung, while the opposite lung is hypoplastic and poorly vascularized. The angiocardiographic study demonstrates the absence of a pulmonary artery with good vascularity of the overdistended lung (Fig. 6-77, upper left). Studies utilizing rapid serial roentgenography have disclosed that the bronchial arterial circulation supplies the poorly vascularized lung.

Experience in three cases indicates that absence of a main branch, when uncomplicated, is usually discovered during routine chest x-ray survey. The condition may be mistaken for a mediastinal tumor. Absence of a main branch has also been recently described in association with cyanotic congenital heart disease, usually tetralogy of Fallot.

**Absence of a Lung (Agenesis).** Absence of a main branch of the pulmonary artery also occurs in lung agenesis. Differentiation from an acquired fibrothorax depends upon the demonstration by bronchography or bronchoscopy of a congenitally absent bronchus. The diagnosis should be suspected if there is an opaque, shrunken hemithorax containing the mediastinal structures, heart, and great blood vessels without a main bronchus. In a 22-year-old patient, in addition to absence of the left pulmonary artery, there was a markedly enlarged pulmonary artery and right branch due to pulmonary hypertension and a patent ductus arteriosus with reversal of flow (Fig. 6-77, lower left). The latter complication makes the ligation of the ductus hazardous. Recently, tracheal compression by the remaining pulmonary artery in an infant with agenesis of the lung was reported. This mechanism may explain the cause of death early in life. In the adult, agenesis of the lung, unless complicated by a congenital cardiovascular anomaly or pulmonary disease, is compatible with a normal life.

**Pulmonary Arteriovenous Fistulas.** A few years ago, the existence of pulmonary arteriovenous fistulas was unknown. Since the advent of safe exploration of the lungs by means of angiocardiography, body section radiography, and fluoroscopic recognition of change

nosis during life in the unruptured state can be made by angiocardiology.

**Associated Anomalies with Aortic Sinus Aneurysms.** Angiocardiography provides the definitive diagnosis of aortic sinus aneurysm (Fig. 6-78C, D). Generalized aneurysmal dilatation of the aortic sinuses was present in all but one of four cases, where only the right aortic sinus was involved. In the cases with coarctation of the aorta, the point of coarctation, the dilated brachiocephalic and collateral arterial branches, as well as the enlarged left ventricle were clearly outlined. In contrast, in a case of pseudocoarctation, although there was an unusually dilated left subclavian artery, an apparent point of coarctation, and a dilated descending aorta, there was no collateral arterial circulation (Steinberg, 1956).

## ANOMALIES OF THE LARGE VEINS

**Anomalous Insertion of Pulmonary Veins.** In 1949, partial anomalous insertion of the right pulmonary vein into the inferior vena cava was first diagnosed during life by angiocardiology and cardiac catheterization. Since then, recognition of totally anomalous pulmonary drainage into the right atrium and its tributaries has also become possible. Diagnosis of these conditions is important, the re-anastomosis of pulmonary veins into the proper atrium in specially selected cases may be life-saving (Sepulveda et al.).

Figure 6-79A shows a classic angiocardio-gram of a patient with a right pulmonary vein draining into the inferior vena cava. The crescentic broad vascular channels of the anomalous right pulmonary vein converging toward the cardiohepatic angle and inferior vena cava are clearly identified.

When anomalous pulmonary veins from the lungs or the whole left lung insert into the left innominate vein, a characteristic roentgen picture results (Fig. 6-79B, C). The abnormal mediastinal and hilar shadows have been likened to a "figure of eight," a "dumbbell silhouette," a "mediastinal mustache," and a "cottage loaf." On angiocardiology, the widened mediastinal and hilar shadows on the left are seen to be due to the dilated common pulmonary venous trunk (persistent left superior vena cava) inserting into the left innominate vein, while on the right side, they are due to the dilated superior vena cava, enlarged be-

# Surgery of pulmonic stenosis with normal aortic root

C. GORDON SELL AND H. WILLIAM SCOTT, JR.

Pulmonic stenosis is one of the most common congenital cardiac malformations. It is frequently encountered in association with dextroposition of the aorta as a part of Fallot's tetralogy, but it also occurs in another large group of cases, in which the aorta has a normal origin from the left ventricle.

Several classifications have been developed for this latter group of lesions. None of them is entirely satisfactory but, for the purpose of clarity in this discussion, an anatomicoclinical grouping is suggested. The true incidence of the various types of pulmonic stenosis is not accurately known. Only in the last few years has it been recognized that many mild instances of pulmonic stenosis exist, for only recently has it become apparent that many patients with murmurs in the pulmonary area, which had been regarded as being functional, have in fact mild degrees of pulmonary stenosis. Previously, it was thought that 60 per cent of patients with pulmonary stenosis and normal aortic root were cyanotic. This estimate is inaccurate as it was based on surgical experiences which dealt naturally with the severe grades. In patients studied by the authors by cardiac catheterization, the ratio of 5 acyanotic patients to 1 patient with cyanosis has been found. The "dome-shaped" type of valvular

stenosis is by far the most commonly encountered anatomic form of obstruction and is probably at least ten times more frequent than is infundibular stenosis or the combination of valvular and infundibular lesions (Fig. 6-82). Fortunately, from the surgical viewpoint, the "scarring" type of valvular stenosis with contraction of the valve ring is very rare.

## INDICATIONS FOR SURGERY

Indications for surgical intervention in patients demonstrated to have pulmonic stenosis with normal aortic root fall, in the authors' opinion, into two categories—emergency and elective. Potts has pointed out that surgical relief of pulmonic stenosis may be required urgently as a lifesaving procedure in certain patients. These are almost invariably young infants who are usually cyanotic and extremely dyspneic when first seen. The evidence for the diagnosis of severe pulmonic stenosis rests on the presence of cardiomegaly, hepato-

fused cusps are divided in the annulus in a bi-radiate or tri-radiate fashion with small scissors (Fig 6-83). Reduction of body temperature to the range of 30 to 32°C and 3 or 4 min of cardiac inflow stasis are the chief requisites of the method.

The Swan procedure has the advantage of direct visual control in division of the stenotic valve, and pressure measurements in patients treated in this manner have shown in most instances very satisfactory relief of the valvular obstruction, with a prompt reduction to normal in right ventricular pressures, a rise in pulmonary arterial pressures, and the elimination of any significant gradient across the valve.

In certain patients, however, the right ventricular pressure may remain elevated after completion of anatomically successful valvulotomy and returns to normal levels only after the passage of weeks or months. This is thought to be due to hypertrophy of the muscular wall of the right ventricular outflow tract which takes time to diminish.

In the authors' opinion, the Swan operation

of transpulmonary arterial valvulotomy under direct vision with hypothermia is the procedure of choice in the definitive relief of pulmonary valvular stenosis on an elective basis. In an initial series of 34 consecutive patients treated in this way by Swan and his associates, there were two operative deaths and excellent clinical results in the survivors. Thus far, in the authors' smaller series, the postoperative results have been equally good.

The Swan procedure has the disadvantages of being a more elaborate and time-consuming operation than Brock's method. While a median sternotomy can be used, Swan prefers bilateral anterior thoracotomy with transection of the sternum. Hypothermia with its inherent hazards and complications, including increased ventricular irritability, postoperative peripheral neuropathies, and subcutaneous fat necrosis, must in itself be listed as a disadvantage. Experience has shown, however, that these risks may be greatly reduced by not lowering body temperature below the range of 30 to 32°C. This range permits interruption of circulation for a period of 4 to 5 min with reasonable safety. Thus

Fig 6-83. Direct exposure and division of stenotic valve by Swan's transpulmonary arterial method. Hypothermia (30 to 32°C) and 3 to 4 min of circulatory stasis are used to permit val-

chest roentgenogram suggested the diagnosis because of anomalous pulmonary vessel at the right base. Angiocardiography (Fig. 6-79D) confirmed the diagnosis by showing the newly recognized "jet sign," a filling defect at the site of insertion of the anomalous veins into the junction of the superior vena cava and right atrium. The filling defect is due to the turbulence created by the anomalous pulmonary venous blood flow.

*Persistence of Left Superior Vena Cava.* Recognition of persistence of the left superior vena cava has become possible with the advent of angiocardiography and cardiac catheterization. Simultaneous injection of Urokon through both arms shows the essential features of the anomaly (Fig. 6-80A). Since publication of this case, persistent left superior vena cava associated with coarctation of the aorta has also been encountered.

## ANOMALIES OF THE CORONARY ARTERIES

*Coronary Arteriovenous Fistulas.* Angiocardiography is not a reliable method of visual-

izing the coronary arteries. However, a circumscribed aneurysm of the coronary artery was visualized, and a continuous apical murmur at the apex of the heart permitted the diagnosis of a coronary arteriovenous fistula. Figure 6-71B shows the angiocardiogram of such a case.

## ATRIAL MYXOMA

Atrial myxomas are of embryonal origin and may be classed as a congenital lesion. A significant advance in cardiac roentgenology was the recognition of intracavitary tumors during life by angiocardiography (Steinberg et al). Fortunately, primary tumors of the heart are rare. When they occur, they may produce bizarre and alarming symptoms, often with intractable heart failure that proves fatal. Four cases were diagnosed with the aid of angiocardiography (Figs. 6-80 and 6-81) which revealed filling defects.

Reports of the successful removal of atrial tumors have been recorded in the literature. Now that the diagnosis can be made by angiocardiography, further improvement in open-heart surgery will result in still more cures.

# Surgical treatment of ventricular septal defects

CONRAD R. LAM

It is a happy circumstance that a chapter on the practical aspects of the definitive surgical treatment of ventricular septal defects can be included in this volume. Until 1954, operations were available only to those patients whose septal defects formed a part of the tetralogy of Fallot and in whom there was diminished pulmonary circulation and right-to-left shunting with cyanosis. Operative treatment consisted of the creation of a systemic-pulmonary shunt (Blalock or Potts operation) or a cautious attack on the pulmonic stenosis, whether valvular or infundibular. Obviously, complete removal of the stenotic element would substitute one pathologic condition for another, i.e., there would be pulmonary hypertension instead of hypotension. Those patients in whom cardiac catheterization revealed an elevated pulmonary artery pressure were manifestly inoperable because cure was not possible without closure of the ventricular septal defect.

In 1954, Lillehei and his associates bypassed the heart by cross-circulation with a human donor and demonstrated that closure of ventricular septal defects under direct vision is feasible. Fortunately, the human donor as well as the heterologous (dog) lung and reservoir methods for bypassing the heart were soon replaced by a simple and inexpensive mechanical oxygenator of the bubble type. In the meantime, Kirklin and his associates had successfully used an oxygenator of the Gibbon type for the closure of ventricular septal defects.

Lillehei summarized the experience of his associates in 1957. They had operated on 154 patients with ventricular septal defects, with a mortality rate of 29 per cent. Obviously, the feasibility of this type of intracardiac surgical procedures is definitely established. However, it has become evident that there is ample opportunity for further refinements. First of all, the operative field is far from dry because, with the conventional bypass, only the venae cavae are occluded and the heart is allowed to beat, with the result that there is a continuous flow of blood from the coronary sinus into the right ventricle through the tricuspid valve. Also, there may be a serious backflow of blood from the aortic valve because of structural or functional insufficiency as a result of distortion. The motion of the beating heart is not conducive to the meticulous suturing indicated for the complete and permanent closure of the septal defect, which lies in such a critical area in proximity to the conduction system and the aortic valve. The answer to these problems lies in the principle of induced cardiac arrest.

In 1955, Lam and his associates reported on experiments in which the heart was stopped with the injection of potassium chloride into the left ventricle. With the brain protected by hypothermia, complicated operations were carried out in the atria and ventricles. Since no pump-oxygenator was available at that time, they had to depend on manual systole to expel the potassium salt from the coronary arteries, and ventricular fibrillation was a com-

Fig. 6-82. Sketch of the most common type of pulmonic stenosis with normal aortic root (Blalock and Kieffer. *Ann. Surg.* 1950.)

megaly, ECG evidence of marked right ventricular hypertrophy and strain, with fluoroscopic and x-ray findings of right-sided cardiac enlargement accompanied by clear lung fields. The classic systolic murmur and thrill in the pulmonary area may be absent or very faintly detectable. In these circumstances, cardiac catheterization and angiocardiography are frequently not feasible and the need for emergency surgical relief of the right ventricular obstruction is extremely urgent.

Indications for surgery on an elective basis for pulmonic stenosis with normal aortic root include patients with cyanosis and dyspnea who, in general, will be found to have right ventricular pressures of 70 mm Hg and over at rest and many of whom will show an ECG picture of right ventricular hypertrophy and strain with a mild to marked degree of cardiomegaly. At the present time, the authors do not feel that surgery is indicated in asymptomatic patients with right ventricular pressures in the range of 70 mm Hg or less with normal heart size and electrocardiographic findings. However, if as rarely occurs, a totally asymptomatic patient has a right ventricular pressure of 100

mm Hg or over, elective operation is indicated.

## SURGICAL TREATMENT

Brock and Sellors (1948) independently recognized the need for a direct surgical attack on the site of obstruction in *valvular pulmonic stenosis*. They devised a transventricular approach whereby a simple valvulotome was passed via a small incision through the valve from below, splitting it transversely. The initial split was then dilated by sounds in an effort to extend the laceration to the annulus. Later Potts (1951) described his ingenious valvulotome with retractable blades and a dilator which functions on a similar principle. Many patients in both the cyanotic and acyanotic groups have been successfully relieved of obstructing valvular pulmonic stenosis by Brock's transventricular approach, both with the original rigid valvulotomes and by the use of Potts' instruments and their modifications. Included among the latter is the valvulotome with three retractable blades designed by Muller et al. Instead of splitting the valve in the Brock manner, Johnson has used a small guillotine knife and made several narrow bites in the valve after hooking it in the blades of the guillotine.

An approach to the stenotic valve by passing a valvulotome with retractable blades through a

of a diverticulum attached to the main pulmonary arterial trunk.

Postoperative catheterization studies in many patients with pulmonic stenosis treated by the various methods of blind instrumentation have shown that all too often a sizable gradient across the valve persists, indicating incomplete relief of the stenotic obstruction. These findings have emphasized the wisdom of monitoring pressures in the pulmonary artery and right ventricle during operation when closed techniques are used, in order to ensure adequate relief of the obstruction by repetitive instrumental splitting of the valve until the gradient is virtually eliminated.

Dissatisfaction with the results of closed methods led Swan (1953) to initiate the use of a method

by temporarily occluding the venae cavae. The

ceedingly important Postoperative hemorrhage must be watched for diligently and treated appropriately by blood replacement, additional protamine, and if necessary, exploration of the chest and pericardium. The maintenance of a clear airway may be difficult, and the use of prophylactic tracheotomy in infants under the age of 1 year has much to commend it.

## RESULTS

Sixty-two operations for the cure of ventricular septal defect have been carried out so far (1957) on 61 patients (one patient was operated on a second time because of early recurrence of the defect). There were 21 deaths in the entire series, giving a mortality rate of 34 per cent. The relationship of age to mortality rate may be seen in Table 6-7. Slightly less than half of the infants under the age of 1 year survived. In children over the age of 3 years, regardless of the other factors, the mortality rate was only 12 per cent.

A significant factor has been the amount of experience of the surgical team with the technical aspects of the extracorporeal circulation procedure. There were 5 deaths in the first 7 patients. These patients received the low flows originally advocated, i.e., 30 ml/kg/min. In the last 55 cases, this flow rate has been doubled, and out of 24 patients over the age of 3 years in this group, there has been only 1 death. Even this death would have been prevented by the more generous dose of protamine sulfate now used routinely.

In the analysis of the first 154 cases in his series, Lillehei found that the degree of pulmonary artery hypertension was an important factor in the recovery rate. He divided the

TABLE 6-8. RELATIONSHIP OF PULMONARY HYPERTENSION TO MORTALITY RATE

| Degree of pulmonary hypertension           | No of cases | Deaths | Mortality rate, % |
|--|-------------|--------|-------------------|
| Moderate (under 60 cm water mean pressure) | 21          | 8      | 38                |
| Severe (over 60 cm water mean pressure)    | 34          | 11     | 33                |
| Extreme (balanced shunt)                   | 7           | 2      | 20                |

patients into two groups, those with severe pulmonary hypertension (70 per cent or more of aortic pressure) and those with moderate pulmonary hypertension (less than 70 per cent of aortic pressure). The mortality rate in 86 cases of the former group was 40 per cent, and in 68 cases with moderate pulmonary hypertension, the mortality rate was only 14.8 per cent. An analysis of the author's series did not indicate a similar relationship. In fact, it turned out that the patients with the higher pulmonary artery pressures did statistically better (Table 6-8). It should be pointed out that the pressures in Lillehei's series were computed from aortic and pulmonary systolic pressures, while the pressures used for comparison in the author's series are mean arterial pressures.

The important thing is whether the pulmonary hypertension is due primarily to flow or to resistance of the vascular bed of the lung. Increased pulmonary flow is revealed by elevation of the pulmonary capillary wedge pressure or the pulmonary vein pressure;<sup>1</sup> x-ray evidence of increased pulmonary vascularity, and electrocardiographic evidence of left atrial and ventricular enlargement. Resistance as the predominant factor is evidenced by pulmonary artery hypertension in the absence of parallel elevation of wedge pressure or pulmonary vein pressure, decreased pulmonary vascularity, and electrocardiographic indication of predominantly right heart enlargement. The fact that there were five survivals in the seven cases in which the pulmonary artery pressure was equal to that of the aorta was

TABLE 6-7. MORTALITY RATES WITH RESPECT TO AGE IN VENTRICULAR SEPTAL DEFECT CLOSURES

<sup>1</sup> This point does not meet with general agreement. Editor.

period is sufficient for the performance of an uncomplicated pulmonary valvulotomy but may be insufficient to deal safely with a more complicated lesion such as infundibular stenosis.

Perfusion of the coronary arteries with oxygenated blood during circulatory arrest with hypothermia has recently been used to enhance the safety of the technique by reducing the effects of myocardial hypoxia. With this modification and perhaps also with the addition of cerebral arterial perfusion, the safety of the Swan technique may be increased.

In the experience of the authors, the incidence of the murmur of pulmonic insufficiency has been higher after the Swan operation than following the Brock procedure. However, follow-up studies of patients with such murmurs have led the authors to believe that they are hemodynamically unimportant. Whether mild pulmonary insufficiency has a higher incidence after triradiate incision of the stenotic valve than with bisection is as yet uncertain.

In the vast majority of cyanotic individuals with an atrial right-to-left shunt and pulmonic stenosis, there is a patent foramen ovale which is kept open by the elevated right atrial pressure. Following a successful pulmonary valvulotomy with reduction of pressures in the right side of the heart, the right-to-left shunt is automatically abolished, resulting in the functional closure of the foramen. In a few cases, however, there is a large defect in the atrial septum, and successful valvulotomy has been followed by a large left-to-right shunt which has necessitated a second operation for closure of the atrial defect.

A practical approach to the problem of atrial shunt with pulmonic stenosis at operation consists of inserting a finger into the right atrium after completing the valvulotomy in order to assess the status of the atrial septum by palpation. If only a small, slitlike valved foramen ovale is present, the authors feel that it can be safely ignored, on the other hand, if a larger atrial defect is present, it should be closed by one of the currently available methods.

The problem presented by the young infant with extremely tight pulmonic stenosis all too frequently constitutes a surgical emergency. In such instances, the authors have not used Swan's technique but have followed the method

described by Potts, in which the heart is quickly exposed through a small left anterior thoracotomy and a cataract knife is passed through the stenotic valve via a stab wound in the right ventricle as a lifesaving measure. After creating a small opening in the valve in this way, the Potts valvulotome and dilator may be used to enlarge the opening. In the few cases treated in this way, the authors have felt that the use of the more elaborate and time-consuming technique of the direct visual procedure with hypothermia was unwarranted because of the precarious state of the infant.

*Isolated infundibular pulmonic stenosis* was first attacked surgically by Brock's closed transventricular punch-resection method. Glover, Kilkin, and a number of other surgeons in addition to Brock have reported satisfactory results in patients with this uncommon lesion treated by "blind" resection. The anatomic complexity of the lesion in infundibular stenosis, however, suggests the need for accurate and complete excision of the obstructing infundibular tissue under direct vision. This may be accomplished by the use of hypothermia and circulatory stasis, but the strict limitation of time permissible for open cardiac surgery with hypothermia alone is a serious objection to intraventricular surgery of any form using this technique. Moreover, Warden et al. pointed out that a preoperatively unsuspected ventricu-

eral of their patients. Accordingly, it seems logical that surgical relief of infundibular stenosis with or without an associated valvular pulmonic stenosis should be accomplished by an open operation using cardiopulmonary bypass with a pump-oxygenator. Under these circumstances, the right ventricular outflow tract may be visualized in its entirety, the stenotic lesions dealt with accurately, and an associated ventricular septal defect, if present, may be closed.

As experience with pump-oxygenators increases, the indications for the use of cardiopulmonary bypass with an extracorporeal circulation will certainly be extended. It is not unlikely that, in the near future, it will be advisable to carry out all types of intracardiac and valvular surgery under direct vision with the aid of a pump-oxygenator.

# Surgical treatment of transposition of the great arteries

THOMAS G. BAFFES

It is hardly likely that the surgical procedures used today for the correction of transposition of the great vessels will be anything more than intermediary operations. However, they serve two important purposes. (1) they alleviate the symptoms to the extent that they avoid invalidism in the patient, and (2) they bring into sharp focus many physiologic and pathologic findings about transposition which might contribute to further progress in its correction. The surgery of transposition, therefore, should be discussed in the light of these contributions.

## **PATHOLOGY OF TRANSPOSITIONS**

Basically, transposition of the great vessels is the result of failure of the embryonic aortopulmonary septum to spiral, with the result that the aorta comes off the right ventricle and the pulmonary artery originates from the left ventricle. As a result, the unoxygenated blood returning via the venae cavae is returned through the aorta to the periphery, while the oxygenated blood from the pulmonary veins is returned to the lungs by way of the pulmonary artery. The systemic and pulmonary circulations are thereby completely isolated from one another—a situation incompatible with life, except for the fact that a certain amount of mixing of the two circulations occurs through an interventricular septal defect, an interatrial septal defect, a patent ductus arteriosus, or combinations thereof. Furthermore, the congenital deformity often is more

complex. Superimposed upon it may be any one of many familiar congenital deformities. Thus, transpositions may be found in conjunction with valvular stenoses of all types, infundibular stenosis, right aortic arch, coarctation of the aorta, dextrocardia, etc. A study of the pathologic conditions found at autopsy in 75 cases of transposition was made in order to classify the types of transposition which might be encountered. Five groups were identified.

*Transposition plus Shunt.* Forty-six specimens (61.3 per cent of the cases studied) were transpositions having only interventricular septal defect, interatrial septal defect, patent ductus arteriosus, or combinations of these additional deformities. There was no obstruction to blood flow through the heart.

*Transposition plus Coarctation of the Aorta.* Eleven specimens (14.7 per cent of the cases studied) consisted of transposition in conjunction with infantile or adult coarctation of the aorta.

*Transposition with Isolated Dextrocardia.* One specimen (1.3 per cent of the cases studied) resembled in all details the simple transpositions in the first group, except that it was a mirror image of that type of heart.

*Transposition with Pulmonary Stenosis.* Twelve specimens (16.0 per cent of the cases studied) had transposition in conjunction with organic pulmonary valve stenosis, bicuspid pulmonary valve, or infundibular stenosis of the right ventricle.

*Transposition with Tricuspid Stenosis.* Five specimens (6.7 per cent of the cases studied) had tricuspid valve stenosis or atresia.

Fig. 6-84. Diagram of cannulations for bypassing the heart with the pump-oxygenator and method of inducing cardiac arrest by the injection of the cardioplegic drug, acetylcholine.

mon complication. However, in a series of 20 animals, only one had refractory fibrillation. Later, the authors began tests with *acetylcholine* as the cardioplegic drug and it was found excellent for the purpose. In the meantime, Melrose demonstrated that *potassium citrate* is useful for inducing cardiac arrest, and this method has been applied clinically by Effler and his associates.

## METHOD

Details of the technic which the author and his associates have used in the repair of interventricular septal defects have been presented in detail (1957), and only a summary will be included here.

The chest is opened through a transverse incision through the 3d interspace and the sternum. After heparinization of the patient, the left subclavian artery and the venae cavae are cannulated (Fig. 6-84) and attached to the appropriate outflow and inflow tubes of the pump-oxygenator system. When a test with the pump running shows that the inflow and outflow are balanced, a non-crushing clamp is placed across the aorta (and also the pulmonary artery for reasons of convenience), and *acetylcholine* in the amount of 10 mg per kilogram of body weight is injected into the aorta

proximal to the clamp. The drug enters the coronary arteries and promptly stops the heart. An incision is then made in the outflow tract of the right ventricle, and the defect is exposed. In a fair number of cases, it will be necessary to divide one or more papillary muscles, so that the septal tricuspid leaflet may be retracted better. The common type of high defect is shown in Fig. 6-85. Closure is effected by placing interrupted sutures which are tied over a pledget of Ivalon sponge. No recurrence of the defect has been noted following this type of closure.

As soon as the intracardiac part of the operation has been completed, the heart is started by removing the aortic clamp. This permits the perfusion of oxygenated blood through the coronary arteries, and the acetylcholine is washed out. The blood which contains large amounts of the cardioplegic drug passes out of the coronary sinus, through the tricuspid valve, and into the open right ventricle, where it escapes during the closure of the incision into the right ventricle. As a rule, an excellent heart beat is present by the time the ventricular suture line is finished. The cannulas are then removed from the venae cavae and subclavian artery, and protamine sulfate solution is injected to neutralize the heparin. A few sutures are placed in the pericardium, and the chest is closed with drainage tubes in both thoracic cavities.

The postoperative care of patients who have had repair of interventricular septal defects is ex-

Fig. 6-85. Exposure of the ventricular septal defect and method of closure with sutures tied over a patch of Ivalon sponge. Note that the sutures are passed through the fibrous tissue of the left ventricular side of the septum rather than the muscular tissue on the right side, to avoid conduction bundle injury.

years. In general, the patients had no post-operative cyanosis at rest and had only slight blueness of the lips and nail beds after exercise. After operation, they also demonstrated marked increase in exercise tolerance and visible increase in muscle mass of the thighs and

calves. Those who had suffered from episodes of syncope, no longer had those attacks. Mental alertness was notably increased. Those who had hepatic enlargement and ascites before operation had decrease in size of the liver and disappearance of the ascites.

## 6-176 CONGENITAL HEART DISEASE

probably because no cases of balanced shunt with marked pulmonary resistance and little or no flow were accepted for the operation.

There have been no late deaths or serious complications in the patients who have lived more than 2 days after the operation, with the exception of the one instance of early recurrence. The clinical improvement following the closure of the shunts has been remarkable. Weight gain in the undernourished children has been rapid. The cardiac status has promptly changed into a normal one. Normal activity has been tolerated within the first few weeks. A surprising dividend has been the rapid change of the radiologic picture of the heart toward one that is essentially normal.

### SUMMARY

The repair of ventricular septal defects is a relatively safe surgical procedure, provided reasonable candidates for the operation are selected and the technical details of the operation are carefully managed. The poorest results are obtained in infants (under the age of 1 year) and in patients with high pulmonary arteriolar resistance. The best results are obtained in children above the age of 3 and in patients with high pulmonary artery flows.

Induced cardiac arrest with acetylcholine as the cardioplegic agent is a valuable adjunct during the cardiac bypass with the pump oxygenator.

# SURGERY OF PATENT DUCTUS AND OTHER DEFECTS

## PATHOLOGIC PHYSIOLOGY

Spontaneous closure of the ductus arteriosus probably occurs in the first 2 weeks following birth.<sup>1</sup> The exact involutional process is not entirely clear. Barclay et al., in their studies on sheep, indicate that the ductus is functionally closed within a few minutes after initiation of pulmonary function. Gross has stated that the variation of the insertion of the ductus away from an acute angle to a more obtuse one would tend to keep it patent. Kennedy and Clark have suggested that inadequate oxygenation of the blood promotes patency of the ductus. Taussig suggests a lack of

ductus is accomplished by a membrane at the pulmonary end. She suggests that such a membrane might rupture with rising systemic pressure and account for the appearance of signs of a patent ductus arteriosus in later childhood or adult life.

Although the physiology and diagnostic features of patent ductus arteriosus are considered in detail in another section of this book (Part I, Chaps. 1 and 2), there are certain features which are of concern to the surgeon in his approach to the problem. Usually, if a ductus is not closed within the first few months of life, it will probably remain patent, and in most cases surgery may be performed after 3 years of age. The so-called *atypical ductus* in infancy, having only a systolic murmur, is a natural phenomenon resulting from the lack of elevation of systolic-diastolic pressure in the systemic system to promote flow during both systole and diastole. With the rise in pressure, the continuous *machinery murmur* is then heard. The size of the ductus varies in diameter from 0.5 to 1 cm and, in length, from practically a contiguous pulmonary artery and aorta to 1 to 1.2 cm in length. Anatomically, a patent ductus may be classified into *cylindrical*, *funnel*, or *window* types. Another important consideration is the early appearance of *pulmonary hypertension* with the large ductus and resultant *bidirectional flow* and reversal of flow. This will be discussed below in more detail (pp 0-162).

The patent ductus arteriosus may be associated with other congenital anomalies. Pulmo-

nary stenosis may be associated with a patent ductus arteriosus and account for a persistent murmur after correction of the ductus. The ductus may serve as a lifesaving measure in the presence of pulmonary atresia and in certain cases of transposition and truncus arteriosus. Finally, a patent ductus may be present distal to a coarctation of the aorta, resulting in cyanotic lower extremities and noncyanotic upper extremities. Although most of the literature is concerned with treatment of patent ductus in children, there has been a gradual increase in experience with adults over the years, and this introduces an additional pathologic and surgical problem in that, in adults, the ductus is more friable and there are often associated degenerative changes both in the aorta and the ductus itself, making for increased hazard in its surgical treatment. Aneurysm of the pulmonary artery is associated with a patent ductus in a significant percentage of cases. It usually is in the main pulmonary trunk. Aneurysms of the ductus itself are rare and consist of dilatation of the aortic end of the ductus, with the pulmonary end being closed. Graham has reported on this aspect.

## INDICATIONS AND TECHNIQUE

There is general agreement that the actual existence of the lesion, patent ductus arteriosus, is indication for surgical intervention. The low mortality associated with operating on infants and children, particularly above 2 years of age, as contrasted with the increased mortality in adults, emphasizes the urgency of correcting this condition in childhood. Contraindications to surgery may be present in those patients in whom some other condition makes surgery extremely hazardous. Secondly, operation below 2 years of age probably should not be done, except in those cases in which there are progressive signs of deterioration and cardiac failure due to the presence of the ductus. Other contraindications would fall in that group in which the ductus is serving a function in association with other congenital anomalies and correction of the patent ductus without recognition of the underlying pathologic condition would result in disaster. Most surgeons agree that treatment of bacterial endocarditis should precede surgical division of the ductus. Finally, the presence of a so-called *atypical ductus*, or ductus with reversal of flow, may be

<sup>1</sup> See Part I, Chap. 2 Editor

It is apparent from this classification that all transpositions cannot be treated in the same manner. In the first three groups, it is possible to attempt to redirect the systemic and pulmonary circulations. In the last two groups, however, the basic difficulty consists of insufficient blood supply to the lung. These patients will respond to standard aortopulmonary or systemic-pulmonary anastomoses. Empirically, the pressure in the pulmonary artery has been utilized to decide which patients should have surgical redirection of the systemic and pulmonary circulations and which should be treated with the shunt operations. *Those whose pulmonary artery pressure is over 200 mm of water receive the former, those whose pulmonary artery pressure is less than 200 mm of water are treated with the latter.*

The problem of finding a suitable method for redirecting the systemic and pulmonary circulations has been a formidable one. Four types of approach to the problem have been evolved. (1) The earliest attempts consisted of methods for enlarging or creating interventricular or interatrial septal defects, combined with forced shifting of blood from one side of the heart to the other by means of vascular anastomoses. These methods, however, did not alleviate symptoms sufficiently. (2) Attempts were then made to divide the aorta and the pulmonary artery at their bases and transfer them to their correct ventricles. These methods generally did not transfer the coronary circulation, and thereby created conditions similar to congenital anomalous coronary arteries. (3) A third approach to the problem utilized hypothermia or extracorporeal circulation to permit opening the right atrium and shifting the interatrial septum in such a way that the two circulations are properly redirected. None of these attempts has resulted in clinical success. (4) The remaining approaches concentrated upon transplanting the venous return to the heart in such a way that the unoxygenated blood from the venae cavae was directed to the lungs and the oxygenated blood from the pulmonary veins was directed to the aorta. This problem has not been entirely solved, but transplantation of the right pulmonary veins and the inferior vena cava is now possible, rerouting approximately 60 per cent of the pulmonary and systemic circulations and greatly improving the peripheral oxygen saturation of

the patient. Such a procedure is being used at the Children's Memorial Hospital in Chicago.

## OPERATIVE PROCEDURE

A curved posterolateral incision is made through the right 5th intercostal space, and the right pulmonary artery, right main bronchus, right pulmonary veins, lateral aspect of the right atrium, and the inferior vena cava are dissected free. A curved coarctation clamp is applied to the lateral aspect of the inferior vena cava, in such a way that blood flow from the inferior vena cava into the right atrium is not impeded. An incision is made in the excluded lip of the cava, and a homologous aortic graft is anastomosed to it. The right pulmonary artery and the right main bronchus are then occluded with umbilical tapes in order to prevent congestion of the right lung during the remaining maneuvers.

A coarctation clamp is applied to the base of the right pulmonary veins, allowing them to be severed from the left atrium with a common pedicle. The opposite end of the homologous aortic graft is then anastomosed to the left atrial stump of the right pulmonary veins. The distal end of the right pulmonary veins is anastomosed to the lateral aspect of the right atrium, part of its wall being excluded with a curved coarctation clamp for that purpose. The temporary umbilical tape ligatures are removed from the right pulmonary artery and the right main bronchus. The right lung is aerated. After the patient has had a few minutes to adjust to the new circulation, the flow of blood from the inferior vena cava through the aortic graft into the left atrium is made obligatory by placing a ligature around the base of the inferior vena cava at its point of entry into the right atrium. The pericardium is repaired, endothoracic drainage is provided, and the operative incision is closed.

## RESULTS

Thirty-eight patients have been operated upon in this manner. Twenty-three survived the immediate postoperative period, an operative mortality of 39.4 per cent. Four patients died after leaving the hospital, of infection or pulmonary hypertension. The remaining 19 long-range survivors have shown very satisfactory clinical improvement. From a preoperative peripheral oxygen saturation of 35 to 50 per cent, they have had increases in oxygenation amounting to 30 to 50 per cent. Their postoperative peripheral oxygenation has ranged from 85 to 93 per cent of capacity.

The youngest patient surviving this operation was 6 weeks of age. The oldest was 12

of Waterman et al on the surgery of patent ductus arteriosus is important as it represents a composite of experience of 49 different collaborators, which in turn represents the work of even more surgeons. The report covered 4,448 operative cases, 552 being eliminated, leaving 3,896 reportable cases, of which 2,929 were performed on children and 967 on adults. The over-all mortality was 2.77 per cent. In the children's group it was 2.3 per cent, and in adults it rose to 5.5 per cent. There was very little difference in the mortality with ligation versus division.

If, however, one introduces the factor of pulmonary hypertension, then the total experience in this group of cases is not sufficient to reach an exact conclusion. It is recognized that, if the shunt reverses from a predominantly

left-to-right flow, then the hazards of interruption of the ductus are increased. Ellis et al. advised against closure of the patent ductus in patients with sufficient pulmonary hypertension to produce an exclusively right-to-left shunt or one in which the right-to-left exceeds the left-to-right shunt. This was on the basis of a 50 per cent over-all mortality in 14 cases exhibiting such a level of hypertension. Cerebode et al reported 11 patients with patent ductus and pulmonary hypertension of whom 10 were operated upon with complete closure, with one death occurring. Attempts to help solve this phase of the problem have been directed toward preoperative occlusion of the ductus by a balloon and temporary occlusion at the time of surgery with measurements of pulmonary artery pressure.

### AORTOPULMONARY SEPTAL DEFECT

Aortic septal defect, aortopulmonary fistula, aortopulmonary defect, or aortopulmonary window are various terms applied to the failure of fusion of the aortic septum dividing the pulmonary artery and aorta. Although this is an extremely rare condition, it is of great importance because of its confusion with a patent ductus, which is so easily correctable surgically, as contrasted to this lesion which is far more difficult to treat. The development of this defect and its medical aspects, together with the diagnostic features, are included in other chapters.<sup>1</sup> In general, however, the clinical appearance of these patients is very much the same as that of patients with a patent ductus, and the final diagnosis is probably best made by *retrograde aortography* or actual placement of the cardiac catheter through the defect, from the pulmonary artery into the aorta. This condition, of course, may also be confused with other causes of continuous murmur in this area, namely, rupture of an aneurysm of a sinus of Valsalva into the right atrium or ventricle or rupture of an aneurysm of the aorta into the pulmonary artery or into the great veins, or finally an anomalous coronary artery draining into a cardiac chamber.

Variations in the anatomic characteristics of the aortopulmonary septal defect run from a tricus arteriosus (in which there is no sep-

tum between the pulmonary artery and the aorta), to a high interventricular septal defect, to an actual aortopulmonary window or defect (in which there is fusion of the septum below the defect, just at the origin of the aorta and pulmonary artery). The defect varies in size from 1 cm or less up to 3 cm, which was the size of one of the cases treated by the authors. The literature has been reviewed by Davis and Cooley. According to the latter, Helkoten (1900) reported the first case in American literature, and at the time of Cooley's publication (1937), 25 more cases had been recorded.

Gross apparently accomplished the first successful surgical approach to the problem of aortopulmonary septal defect. In 1948, he ligated such a defect with a tape ligature, and the patient survived with the defect closed. The next method of treatment parallels the development of surgical treatment of patent ductus, namely, division of the communication, with suture of the sectioned communication. One great difference, however, in the comparison of these two lesions, in so far as this surgical approach is concerned, is that, in the aortopulmonary window, the posterior wall is extremely thin and easily entered during dissection. Also, it may be difficult to get enough tissue on either side without compromising one or the other vessels.

Successful cases have been reported by Fletcher, using division and suture, and Davis

# *Surgical treatment of patent ductus arteriosus and aortopulmonic defects*

WILLIAM S. DYE AND ORMAND C. JULIAN

## PATENT DUCTUS ARTERIOSUS

The surgical correction of a patent ductus arteriosus has become a standard procedure throughout the world. The development of this procedure constitutes one of the early chapters in the history of surgery for cardiac and extracardiac lesions. Historically, the early studies centered around the successful ligation of a patent ductus, with subsequent development of division and suture of the patent ductus. The most recent studies have been directed toward the problem of the patent ductus associated with pulmonary hypertension.

Munro (1907) first suggested ligation of the ductus arteriosus. Graybiel et al (1938) reported one of the first attempts to ligate a patent ductus. This was in a patient with bacterial endocarditis, and death occurred on the fourth postoperative day. Gross and Hubbard (1939) reported the first successful ligation of a patent ductus arteriosus. In the same year, Gross reported again a summary of 4 surgically treated cases, and later (1940) reported his experience with 10 cases. Additional successful cases were reported by Jones et al (1940). Johnson et al (1942) reported 7 cases and outlined the hazard of the posterior wall dissection. They reviewed a death from hemorrhage in 1 case. They suggested more extensive dissection of the aorta and intrapericardial exposure of the pulmonary artery, if needed. Touroff in the same year described his experiences with the infected patent ductus arterio-

sus. The question of incomplete closure or subsequent recannulization following ligation of a ductus arose, and Gross (1944) reported, in addition to 14 cases treated by ligation, 14 subsequent cases with complete division, making a total of 28 cases in whom recannulization took place. Blalock had reported good success with simple ligation, however, using double ligation and transfixion.

Touroff had previously divided the ductus (1942), although it was not deliberate. This was done in a case of infected patent ductus, and the division was done during control of an inadvertent tear. Jones (1947) reported 61 cases, 53 ligated and 8 divided. In the ligated cases, 5 had a return of the murmur immediately and 5 subsequently. In the 8 cases, in which the ductus was divided, 7 survived with no recurrences of the murmur. In the same year, Gross reported further experiences with division of the ductus, and at that time reported 90 cases with 2 deaths. Potts (1948) first reported a new clamp for surgical division of the ductus, and his modification of Gross' technique for division, utilizing the multiple-tooth ductus clamp that has been widely used subsequently. During the first 10 years of development of surgery of patent ductus arteriosus, it became commonplace for surgeons over the country to approach the problem, and the trend was definitely away from multiple ligation to division of the ductus.

of Waterman et al. on the surgery of patent ductus arteriosus is important as it represents a composite of experience of 49 different collaborators, which in turn represents the work of even more surgeons. The report covered 4,418 operative cases, 552 being eliminated, leaving 3,866 reportable cases, of which 2,929 were performed on children and 937 on adults. The over-all mortality was 2.77 per cent. In the children's group it was 2.3 per cent, and in adults it rose to 5.5 per cent. There was very little difference in the mortality with ligation versus division.

If, however, one introduces the factor of pulmonary hypertension, then the total experience in this group of cases is not sufficient to reach an exact conclusion. It is recognized that, if the shunt reverses from a predominantly

left-to-right flow, then the hazards of interruption of the ductus are increased. Ellis et al. advised against closure of the patent ductus in patients with sufficient pulmonary hypertension to produce an exclusively right-to-left shunt or one in which the right-to-left exceeds the left-to-right shunt. This was on the basis of a 50 per cent over-all mortality in 14 cases exhibiting such a level of hypertension. Cerebode et al. reported 11 patients with patent ductus and pulmonary hypertension of whom 10 were operated upon with complete closure, with one death occurring. Attempts to help solve this phase of the problem have been directed toward preoperative occlusion of the ductus by a balloon and temporary occlusion at the time of surgery with measurements of pulmonary artery pressure.

### AORTOPULMONARY SEPTAL DEFECT

Aortic septal defect, aortopulmonary fistula, aortopulmonary defect, or aortopulmonary window are various terms applied to the failure of fusion of the aortic septum dividing the pulmonary artery and aorta. Although this is an extremely rare condition, it is of great importance because of its confusion with a patent ductus, which is so easily correctable surgically, as contrasted to this lesion which is far more difficult to treat. The development of this defect and its medical aspects, together with the diagnostic features, are included in other chapters.<sup>1</sup> In general, however, the clinical appearance of these patients is very much the same as that of patients with a patent ductus, and the final diagnosis is probably best made by retrograde aortography or actual placement of the cardiac catheter through the defect, from the pulmonary artery into the aorta. This condition, of course, may also be confused with other causes of continuous murmur in this area, namely, rupture of an aneurysm of a sinus of Valsalva into the right atrium or ventricle, or rupture of an aneurysm of the aorta into the pulmonary artery or into the great veins, or finally an anomalous coronary artery draining into a cardiac chamber.

Variations in the anatomic characteristics of the aortopulmonary septal defect run from a truncus arteriosus (in which there is no sep-

tum between the pulmonary artery and the aorta), to a high interventricular septal defect, to an actual aortopulmonary window or defect (in which there is fusion of the septum below the defect, just at the origin of the aorta and pulmonary artery). The defect varies in size from 1 cm or less up to 6 cm, which was the size of one of the cases treated by the authors. The literature has been reviewed by Davis and Cooley. According to the latter, Hektoen (1900) reported the first case in American literature, and at the time of Cooley's publication (1957), 25 more cases had been recorded.

Gross apparently accomplished the first successful surgical approach to the problem of aortopulmonary septal defect. In 1948, he ligated such a defect with a tape ligature, and the patient survived with the defect closed. The next method of treatment parallels the development of surgical treatment of patent ductus, namely, division of the communication, with suture of the sectioned communication. One great difference, however, in the comparison of these two lesions, in so far as this surgical approach is concerned, is that, in the aortopulmonary window, the posterior wall is extremely thin and easily entered during dissection. Also, it may be difficult to get enough tissue on either side without compromising one or the other vessels.

Successful cases have been reported by Fletcher, using division and suture, and Davis

<sup>1</sup> See Chaps 2 and 3, Editor.

■ contraindication if the pulmonary hypertension remains the same or is elevated after temporary closure of the ductus.

The technique used in the authors' experience is based on the work of Gross and modifications by Potts and, in certain complicated cases, follows the suggestions of Conklin and Watkins, Jones, and Crafoord. Surgical exposure is through a posterolateral incision, and entrance to the thoracic cavity is through the 4th interspace. The authors are impressed by the increased safety of using the *posterolateral incision* as contrasted to the anterior submammary incision.

Following retraction of the lung anteriorly, the parietal pleura is incised over the anterolateral aspect of the aorta. The vagus nerve is immediately identified and dissected free and retracted. In most of the authors' cases the aorta is dissected free just distal to the subclavian artery, so that the posterior aspect is completely dissected, and cord tapes are placed superiorly and inferiorly to the ductus.

The vagus nerve is identified at the point where the laryngeal nerve comes off and the recurrent laryngeal nerve is exposed as the inferior aspect of the ductus ■ dissected. Reflection of the pocket or lappet of pericardium on the anterior aspect of the ductus is accomplished by sharp dissection, as emphasized by Potts. Section of the fibrous and areolar tissues above and below the ductus is also accomplished by sharp dissection. Retraction of the aorta anteriorly may facilitate some of the dissection along the posterior aspect of the ductus, since it is in this area that blunt dissection by curved instruments may result in disaster, with tearing of the ductus. Superiorly, there is a firm fibrous attachment which has been labeled the *ligament of Gross*. A ductus which often appears quite short at first may, after the completed dissection, be of adequate length for routine clamping and division. Following the isolation of the ductus, angled ductus clamps, as designed by Potts, are applied to the pulmonary and aortic side. It is important to place the clamp as close to and encroaching on the wall of the pulmonary artery and the aorta as possible to provide adequate length between the clamps for division and suture. Two clamps may be used on either side. In the majority of cases, the authors have used the single clamp on each side and have found it satisfactory. Usually the aortic stump is closed first. Sutures are accomplished with a running 5-0 Deknatel suture. Following release of the aortic clamp, the bleeding is controlled by pressure, and suture of the pulmonary stump is accomplished in a similar fashion. The pleura is left open posteriorly in the majority of cases. The chest is

closed with water seal drainage, even in children.

The foregoing technique may be applied to most cases of patent ductus arteriosus. In certain unusual circumstances, other modifications of the technique may be used. In the event of severe hemorrhage from a torn patent ductus, previous dissection of the aorta, as described above, facilitates the immediate cross-clamping of the aorta, as previously described by Crafoord. A ductus clamp, placed on the proximal pulmonary side, controls the hemorrhage and facilitates closure of the rent in the aorta. This method may be used particularly in adults with a very short wide ductus ■ a method of choice, although the use of hypothermia as an adjunct is recommended. However, in one adult case, as an emergency, the aorta was clamped without hypothermia to control hemorrhage, and cross-clamping of the aorta for 50 min resulted in no undue complications. Another method in the short ductus is the use of the Potts-Smith aortic clamp, as described by Conklin and Watkins and Potts. This clamp, by virtue of its partially occluding the lateral wall of the aorta provides more length of the ductus and facilitates suture and division of the ductus at its entrance into the aorta without completely occluding the flow through the aorta itself. Finally, although this method should never be used as one of choice, simple ligation with the addition of suture ligatures may be employed. The use of simple ligature, such as an umbilical tape or heavy silk, probably results in a fairly significant incidence of recannulization and also, in the wider ductus, carries a great hazard of cutting through the wall of the ductus. Recently, partial occlusion of the ductus with subsequent reentry of the chest and complete division has been carried out in certain cases of atypical patent ductus with pulmonary hypertension in order to avoid the results of sudden occlusion of the patent ductus in these cases.

## RESULTS

The over-all good results and low mortality associated with division of a patent ductus arteriosus, particularly in children, leaves no doubt in most physicians' minds of the feasibility and advisability of this procedure. The results in a large series, in children, show a consistent low mortality associated with the procedure, and in most cases it is less than 1 per cent. Since there is no question about the ultimate results of an uncorrected patent ductus of any size, recommendation for surgical treatment of the condition in childhood seems without question. This applies, of course, to the so-called *typical patent ductus*. The report

## Experimental Studies on Cardiopulmonary Bypass

KARL E. KARLSON AND  
JACKSON H. STUCKEY

## Clinical Studies on Open-heart Surgery and Cardiac Bypass

RALPH A. DETERLING, JR.

### HYPOTHERMIA

Hypothermia finds application in heart surgery because it reduces metabolic rate. When employed during anesthesia, it slows all life processes, causing profound depression as low temperatures are reached. With sufficient cooling, the heart beat stops and metabolism almost ceases, yet recovery is still possible, even from near-freezing temperatures. The surgeon who employs hypothermia may, theoretically at least, simply select the degree of metabolic slowing that he needs and then lower the temperature to the proper level. All degrees of cooling, down to near freezing, have been used clinically. The effect of hypothermia is striking, and its use has exerted considerable impact on the development of cardiac surgery. There are still technical difficulties and hazards associated with profound cooling, nonetheless, which limit its full use at present.

### HISTORY

A start in the use of hypothermia for cardiac surgery was made by McQuiston and by

Potts, who advocated mild cooling of infants undergoing surgery for cyanotic heart disease, but the big advance was made by Bigelow and Boerema, independently, in 1950, who demonstrated experimentally that open-heart surgery could be performed under hypothermia and with temporary cardiac inflow interruption. Clinical application of this technique began in 1952 (Lewis and Taufic), and shortly thereafter the method was widely employed to repair atrial septal defects and then isolated pulmonary stenosis. However, the time allowed for open-heart repair was limited with this simple technique to 1 to 10 min at temperatures that were safely attained (28 to 30°C), and this was not enough for more complicated repairs.

Stimulated by the achievements obtained with hypothermia, work with extracorporeal circulation, which dated back to Gibbon's studies in the 1930s, went on at an accelerated pace, soon pump-oxygenators were being employed at several medical centers for open-

a contraindication if the pulmonary hypertension remains the same or is elevated after temporary closure of the ductus.

The technique used in the authors' experience is based on the work of Gross and modifications by Potts and, in certain complicated cases, follows the suggestions of Conklin and Watkins, Jones, and Crafoord. Surgical exposure is through a posterolateral incision, and entrance to the thoracic cavity is through the 4th interspace. The authors are impressed by the increased safety of using the *posterolateral incision* as contrasted to the anterior submammary incision.

Following retraction of the lung anteriorly, the parietal pleura is incised over the anterolateral aspect of the aorta. The vagus nerve is immediately identified and dissected free and retracted. In most of the authors' cases the aorta is dissected free just distal to the subclavian artery, so that the posterior aspect is completely dissected, and cord tapes are placed superiorly and inferiorly to the ductus.
